THE ADVANCING KNOWLEDGE OF SPINAL ANESTHESIA

DANIEL H. BESSESEN, M.D.
Minneapolis

THE use of spinal anesthesia on the head, neck and thorax has been so entirely contrary to our former interpretation of the action of spinal anesthesia, that the established theories of the action of novocaine on the spinal and nerve tissues must be removed before it can be considered safe to administer this form of anesthesia on the higher regions of the body. The mere fact that the novocaine may be introduced into the spinal canal and in any one case produce general anesthesia without death is sufficient to demand explanation if we are to cling to older hypotheses.

It was formerly thought that respiratory and cardiac paralyses were responsible for deaths from this form of anesthesia. This, we now know, is not the case. Deaths which result from subarachnoid nerve blocks are due to cerebral anemia from fall in blood pressure and may be prevented by the Trendelenburg position. Even if no fluids are injected to bring the blood pressure back to normal, the pressure is found to rise again on change of position in those few cases (5 per cent) in which it falls to dangerous levels to within ten or twenty millimeters of the former level measured before the introduction of anesthesia.

To properly explain this action, let us review the studies made on the effect of novocaine on sensory and motor nerves. These indicate that motor nerves are not affected by novocaine in the dilution required to deaden sensory nerves. It is true that sensory stimuli aid in maintaining circulation and respiration, but there is sufficient automaticity in these functions to keep them operating in the absence of sensory stimuli. The distribution of novocaine over the sensory nerves of the entire head, neck and thorax may put the and respiration, if the blood pressure is high patient to sleep but will maintain the circulation enough to nourish the upper nerve centers.

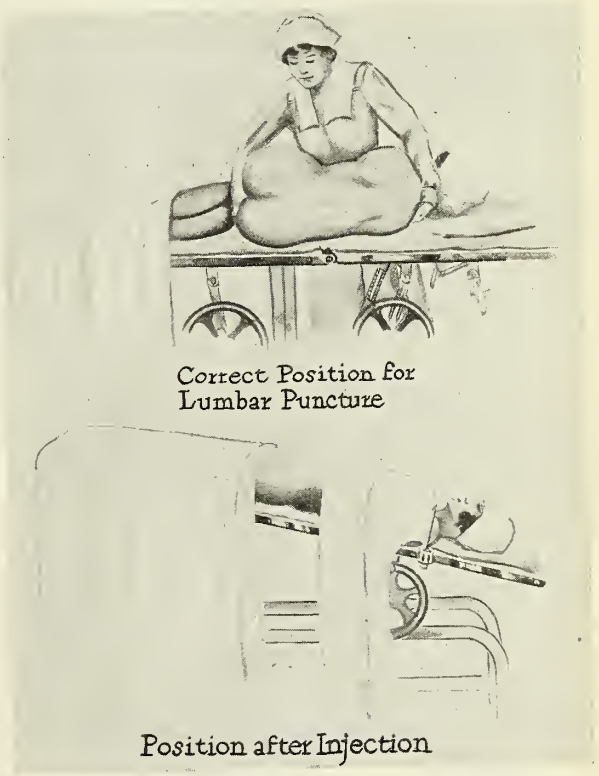

Fig. 1. The position illustrated in the upper drawing is that permitting the greatest ease in performing lumbar puncture. After withdrawing spinal fluid and reinjecting the anesthetic, the patient is placed in the position illustrated in the lower drawing.

When one adds to these physiologic explanations, the anatomic fact that the ligamentum denticulatum divides the posterior (sensory) portion of the spinal canal from the anterior

26011

(motor) portion and that it is into the posterior (sensory) portion that the novocain is injected, it becomes more comprehensible how spinal anesthesia may be applied to the upper portions of the body without danger of death.

The diaphragm is no longer accepted as the upper level of safe spinal anesthesia. The blood pressure is no longer taken as the index of the safety margin of the patient. We are coming more and more to rely on Labat's statement that the safety of spinal anesthesia rests on the Trendelenburg position alone, has nothing to do with the distribution of the novocaine in the nerve centers and need not require more than passing attention to the blood pressure.

The contraindications for the use of this anesthetic are being limited to cerebral disease, infections which may contaminate the spinal puncture and conditions prohibiting the use of Trendelenburg position.

While this advancing work and these changing interpretations broaden the scope of spinal anesthesia and make more comprehensible its application to all fields of the body, we must remember that the use of these methods requires expert care and attention. We must learn to accept these changes in physiologic knowledge and realize that in this way we are approaching a standardization of novocaine nerve block more nearly ideal. There still remain the numerous advantages of spinal anesthesia, but we must not be fanatic in its application to all cases regardless of circumstances—because we must bear in mind that the patient comes to us to get well. Therefore, the best technic and the proper methods suitable to that particular case are the ones to select for administration.

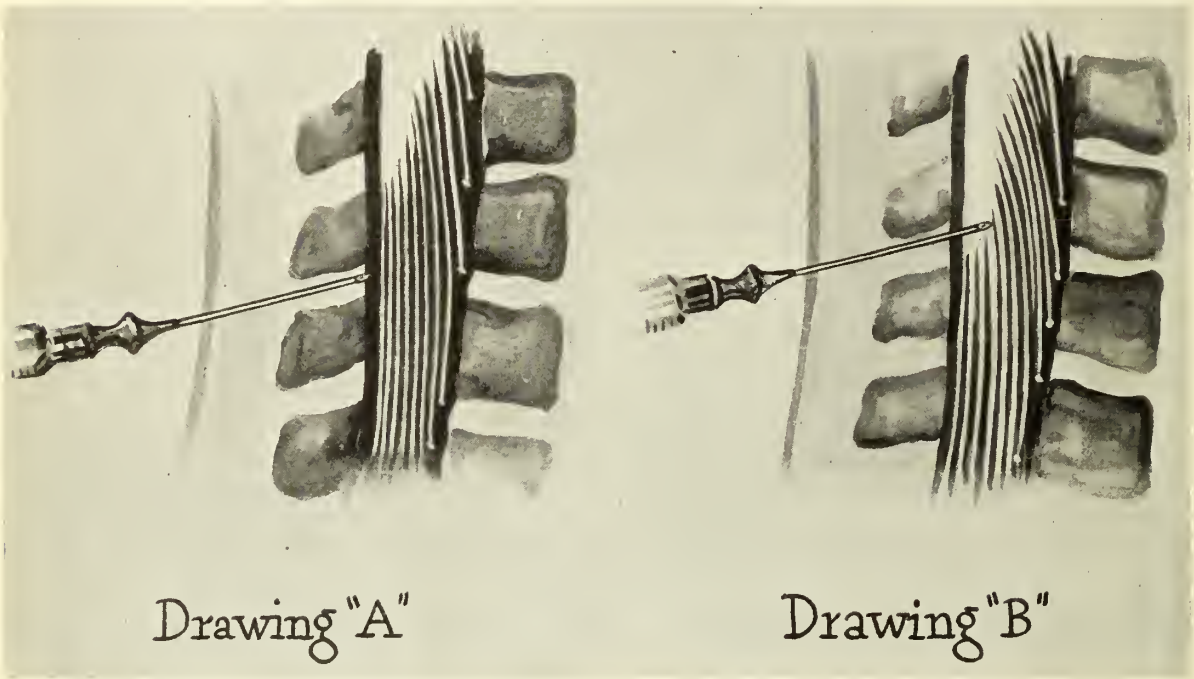

Fig. 2. In drawing "A" is shown the commonest error in technic—the needle is half in and half out of the dura. The spinal fluid will flow out, but the anesthetic will not usually pass into the dural canal.
Drawing "B" illustrates the better placement of the needle, well into the spinal canal. Properly, the bevel of the needle should be within the dura, posterior to the ligamentum denticulatum, thus allowing the novocaine to come in direct contact with the sensory nerve roots.

The technic of spinal anesthesia is departing from stock solutions and from solutions of lighter or heavier specific gravity than the spinal fluid. The best procedure is that described by Evans—the dissolving and reinjecting of one to two and a half decigrams of novocaine in four to eight cubic centimeters of spinal fluid into the spinal canal. The amount of drug and the volume of spinal fluid determine the level of anesthesia. With the larger dosages, the level will rise higher and the length of anesthesia be slightly longer; with larger volume, a wider distribution will be obtained.

The duration of anesthesia still remains at

approximately 60-90 minutes and is suitable for most operations of that expected length of time. The relaxation of muscles and relative bloodlessness of the field make the operative technic much more rapid than under any other form of anesthesia.

These advances in our present knowledge of spinal anesthesia are being heralded with enthusiasm by many of the outstanding surgeons of the world. We can only stand in awe at the marvels of nature as applied to surgical maneuvers.

DR. FLORENCE RENA SABIN WINS AWARD

To that large and constantly increasing number of women seeking professional careers, the announcement by Pictorial Review that the winner of its annual Achievement Award of $5,000 for the year 1928 is Dr. Florence Rena Sabin, fellow of Johns Hopkins University, and member of the staff of the Rockefeller Institute for Medical Research, will prove encouraging.

This award, which is now in its seventh year, is made annually to the American woman, by birth or naturalization, who, in the opinion of a distinguished committee, has made the most distinctive contribution of the preceding year to the fields of American art, science, or letters.

Dr. Sabin has received it for her splendid contributions to mdical science, which include a complete study of the nerve-centers; the discovery of the origin and processes of the lymphatic system; the discovery of the development and processes of the blood-cell; the discovery of the functions of the monocyte, the white blood-cell which bears so directly upon the study of the tubercle bacillus and its effect on the human system.

These discoveries were made by Dr. Sabin in her own original research. Working with her associates, she had also had much to do with the analysis of the tubercle bacillus, and with the research work that is going forward toward a complete cure for this destroyer of the human tissues.

But what is most interesting to the women of to-day is that Dr. Sabin, by her genius and her concentration to her high purpose, has made it easier for all women who wish to enter the field of science with the hope that they, too, may some day reach the apex of achievement. It is an established truth that a way once hewn is easier for those who would follow after. Where one has been it is easier for others to venture. And Dr. Sabin's career has been a series of first adventures for women.

She was the first woman to be admitted and to graduate from Johns Hopkins Medical University. She was the first woman to be admitted as an intern in the Johns Hopkins Hospital. She was the first woman to be a member of its staff. She was the first woman to be a member of the teaching staff of Johns Hopkins Medical University, where she was professor of histology. She was the first American woman to be admitted to European research laboratories, working side by side with men in Italy and in the laboratories of Leipzig and Heidelberg. She was the first and is yet, to-day, the only woman to be made a member of our National Academy of Science, and was also the first woman to become a member of the Rockefeller Institute for Medical Research.

By the steady, quiet force of her ability for original work, her consecration to that work, she has won her way to a position in the world of science second to few men. Dr. Simon Flexner, president of the Rockefeller Institute, declares her to be the greatest living woman scientist and one of the foremost scientists of all time.

Dr. Sabin is the sixth American woman whose name has been added to the roster of Pictorial Review's Hall of Fame for Women. Previous awards have been made to Mrs. Edward MacDowell, for her work in establishing at Peterboro, N. H., a colony where artists may go to work in felicitous surroundings at small cost; to Mrs. Cora Wilson Stewart, for the establishment of the Moonlight Schools in the Southern mountains, where thousands of American men and women have been brought out of the darkness of illiteracy; to Miss Sara Graham-Mulhall, who has accomplished much toward the restrictions of the drug traffic in this country; to Miss Eva Gallienne, for founding the Civic Repertory Theater in New York, whereby the entire country has been stimulated to the need for good drama at a price that all can afford; to Miss Martha Berry, who established and maintained the Berry Schools at Rome, Ga., where over two thousand boys and girls of the Southern rural districts have been able to work their way to an education that would have otherwise been denied them.

The members of the Award Committee are: Senator Arthur Capper of Kansas, Mr. Otto H. Kahn of New York, Mrs. Mary Roberts Rinehart, Mr. Clark Howell of the Atlanta Constitution, Miss Ida Tarbell, Miss Mary Woolley, president of Mt. Holyoke University; ex-Senator James D. Phelan of San Francisco, Mr. Augustus O. Thomas, president of the World Conference on Education; Mr. Carl Sandburg, Mr. John Farrar, literary editor; Mrs. Charlotte Perkins Gilman, Madam Louise Homer, Dr. Henry Goddard Leach, editor The Forum; Mr. Edwin Markham, Mrs. Henry W. Peabody, Mrs. Edith Nourse Rogers, member of the House of Representatives; Mrs. John F. Sippel, president of the General Federation of Women's Clubs, and Mr. Walter L. Clark.

SPINAL ANESTHESIA*

A. E. Olson, M.D.
Duluth, Minnesota

IT is believed that spinal anesthesia, like many great discoveries, resulted from an accident. Dr. J. L. Corning, of New York City, in 1885 produced temporary motor and sensory paralysis of the lower extremities while giving a therapeutic extraspinal injection of cocain. In 1891 Quincke established lumbar puncture as a diagnostic and therapeutic procedure. In 1899 Bier published the results of eight anesthesias which he had practised upon himself, his assistant and six patients. In spite of Bier's warning, this discovery was followed by widespread use. Spinal anesthesia was then soon abandoned due to the poor results occasioned by a lack of understanding of its very definite indications, contraindications and technic.

No method of anesthesia yet discovered has had such a rocky course as the spinal method, and it is my opinion that it is not thus far firmly established. Its long history of use and disuse is in marked contrast with the short, rather stable history of ethylene gas. This can all be explained by: (1) the fact that novocain though discovered in 1904 was not recognized generally as the safest intradural drug until a comparative study was made by Cary Eggleston and Robert A. Hatcher in 1919; (2) that the physiology involved in the sudden drop of blood pressure was not understood and therefore the drop could not be prevented. Even today many surgeons have not been convinced of the superiority of novocain.

Wayne Babcock,[1] of Philadelphia, has been one of the greatest proponents of lumbar anesthesia, both in experimental and clinical work, in this country. In 1911 he reported the results of 350 inductions, and in February, 1926, he recorded the results of over 20,000 inductions. In many European clinics the method is used extensively. Dr. B. Koch, Professor of Surgery at the University of Bratislava, with whom I worked for a short time, had used it in a series of over 6,000 cases and as is the case with Babcock, in 90 per cent of his operations below the diaphragm. At the present time it is used throughout the United States by many surgeons. It is our opinion that several years must elapse before its comparative value as an anesthetic will be determined. In the following review you will note that the indications, contraindications and the technic are very definite. One can blame a death under general anesthesia upon the drug, but under spinal anesthesia a mortality is usually to be blamed upon the surgeon (Babcock[1]).

The known indications may be classified as follows:

(a) *General*

1. Operations below diaphragm only, preferably below the umbilicus (Labat[7]), (Meeker[8]).
2. Age limits. Meeker states that children under sixteen years of age are usually not suitable subjects. Senility associated with debility calls for decreased dosage and often it is advisable to use a local anesthetic where degeneration of the vital organs is evident.
3. Systolic blood pressure must be over 100.
4. When general or local anesthesia cannot be used for any reason and this form is not contraindicated.
5. For diagnostic purposes when muscular relaxation allows more accurate localization.

(b) *Special*

1. Acute abdominal infections such as appendicitis, perforated gastric or duodenal ulcer or obstructive ileus.
2. Cases with high blood pressure not showing marked myocardial changes. Spinal anesthesia should be avoided unless sure of the heart.
3. Cases in which a general anesthetic is dangerous. (I have in mind a patient with chronic bronchitis, marked rectal prolapse, extreme toxemia from gangrene below the middle of the thigh, who under spinal anesthesia made an uneventful recovery following high amputation.)
4. Patients with renal dysfunction, high blood urea, albumin or casts.
5. Cases of acute or chronic respiratory infection. (We have operated several of these successfully.)

*Read before the annual meeting of the Interurban Academy of Medicine, Superior, Wisconsin, November 20, 1929.

6. In the field of operative obstetrics, including cesarean section (Pitkin[9]).

7. In many general diseases including diabetes, pneumonia, tuberculosis, eclampsia, complicating surgical conditions.

8. Operations such as prostatectomies, amputations, hernias, in suitable subjects. (We have used it often in reducing strangulated hernias.)

Contraindications:

Generally speaking, this form of anesthesia is contraindicated in shock, depression or hypotension from any cause. The failures are probably due in most cases to an unwise selection of the patient, the drug, the dosage or technic (Evans[4]).

Specifically, the contraindications may be listed as follows:

1. Cardiac embarrassment from any cause.

2. Mechanical limitation of the respiratory space (fluid).

3. Organic involvement of the cerebrospinal nervous system, such as brain tumor, intraspinal hemorrhage, cord tumor, or meningeal involvement.

4. Patients having great abdominal distention, marked jaundice, or extreme obesity are poor anesthetic risks. They are unable usually to withstand a sharp fall in blood pressure. Local anesthesia is here preferred.

5. Septicemia with positive blood culture.

6. Suppuration at site of puncture.

The greatest advantage of spinal anesthesia is in its application in some emergency operations where there has been no time for adequate preparation. I recently operated for a perforated duodenal ulcer. The patient also had a marked bronchiectasis. By using intravenous saline and adrenalin to combat the shock we were able to administer spinal anesthesia successfully. We did not use local anesthesia because the patient was apprehensive and complete relaxation was necessary.

The complete muscular relaxation facilitates the operative work. When properly administered there is very little metabolic disturbance or interference with the normal functioning of the heart, lungs, kidneys and intestines. Nourishment can be given following operation. It has been stated that post-operative gas pains are less noticeable. This has not been our experience. We, however, believe that post-operative shock is less.

The greatest disadvantage of this form of anesthesia is the too frequent appearance of danger signals during the anethesia. When the vasoconstrictors give way it is with a suddeness that is distracting to the operator. Even after carefully selecting the subject it is not always possible to know in which case the symptoms of collapse with pallor, sweating, distress, respiratory and cardiac failure will occur. The fact that the dose once injected cannot be recalled or prevented from acting and that the patient's life so closely depends upon the accuracy of dosage and skill of the surgeon, certainly should limit the indiscriminate employment of spinal anesthesia. After all, the one real disadvantage in this method of administration is that the anesthetic cannot be administered gradually until the stage of surgical anethesia is reached. The full dose must be administered at one time (Meeker[8]).

Mentally unstable patients are very apprehensive; they are not of the "local type." If the operation is to be prolonged, haste may lead to error. Hemorrhage has resulted from imperfect hemostasis due to the anemia at the site of operation accompanying the fall in blood pressure. Headache occurs occasionally. It may result from a decreased intraspinal pressure due to a leak at the puncture site (Pitkin[9]), an increased pressure (Jackson[5]) or to the presence of chemical agents in the needle or syringe incident to sterilization, which are injected into the lumbar sac, where they serve as irritants. It is a well known fact that headaches occur frequently following diagnostic lumbar puncture as well as after the injection of sera for the treatment of meningeal disease. Ocular palsies and meningeal infection are mentioned in the literature but we have not observed them.

It is important therefore that before using intradural injection one should understand the physiology and technic involved.

The physiological action of the drug depends upon the nerve roots involved and the extent of their involvement. When the drug is injected the feet and perineum are first affected. As the drug spreads, the anesthesia extends up the legs and body to a level corresponding to the highest nerve roots affected. The posterior or sensory roots are more completely anesthetized than the anterior. The drug also diffuses more readily over the posterior than over the anterior roots. Any anesthetic to be successful should produce

two effects, namely, loss of pain combined with muscular relaxation. The first is essential for the operation; the second is desirable that the operation may be done with greater facility.

To repeat, the physiology of intradural anesthesia is that of a transient root interruption, chiefly affecting the posterior roots, causing loss of tactile, muscle, and temperature sense. The anterior roots are also blocked, causing a temporary motor paralysis. The anterior root block affects also the white rami communicantes. This is the most unfavorable and hazardous action of the drug because it causes a temporary vasomotor paralysis. Babcock aptly states that for animals which sit or stand erect a vasoconstrictor system is essential. A snake has no vasomotor system, and when suspended by the head may suffer and finally die from failure of blood to ascend to the heart. A high spinal anesthesia produces the same condition when the head is raised or even placed on a level with the rest of the body. The white rami are associated with the anterior roots from the second thoracic to the third lumbar roots. Obviously, if only the lower lumbar and sacral roots are affected there will be very little effect on the blood pressure. However, if the higher roots supplying the great splanchnic vessels or those above are anesthetized, there will be a marked drop in blood pressure usually lasting from fifteen to thirty minutes (Babcock[1]).

It is evident that a precise technic must be followed in order to obtain the maximum efficiency with a minimum of danger. This will conveniently be divided into preoperative, operative and postoperative stages.

Our preoperative procedure is to give two allonal tables (each 2⅔ gr.) one hour before operation. Experimental study shows that barbital is a very definite antidote to novocain poisoning. This drug is therefore used routinely by many surgeons instead of allonal, 10 grs. being given (Kelly[6]). However, the novocain is used in such small amounts that toxic effects are rarely noted. We have not encountered novocain poisoning in over fifty cases and there is no record of its occurrence up to the present time at St. Luke's Hospital. One half hour before going to the operating room, the patient is given morphine gr. ¼ and atropine gr. 1/150 hypodermically. It is important that sedatives be administered in sufficient amount to counteract the fear accompanying the spinal anesthesia.

Minor preoperative details may be summed up as follows: An enema should be given at least three hours before operation and in rectal and gynecological work it is important that this interval be longer. The eyes should be covered. The patient should be taught to breathe deeply to combat nausea during operation. He is allowed to eat a light supper, but on the morning of the operation we prefer an empty stomach for two reasons: (1) because the nausea during operation may be accompanied by vomiting; (2) this form of anesthesia must often be supplemented by a general anesthetic.

Just before operation the blood pressure is recorded. Ephedrine is given hypodermically, usually 50 mgms. of the hydrochloride at the time of spinal puncture. It may be used with the novocain locally prior to puncture. The height of puncture is determined by the site of operation, the first lumbar space being used for upper abdominal, and lower lumbar spaces for operations at lower levels. Many operators lower the head of the table until the desired anesthetic level is reached. Novocain is put up in ampoules of 50-100 mgms. and we usually determine the dosage on the basis of 10 mgms. of drug to every 10 pounds of body weight. For higher anesthesia and more prolonged action more drug is needed, occasionally 200 mgms. being given in gallbladder and stomach surgery. We rarely use more.

A small Pitkin needle (gauge .22) is used to prevent leakage of spinal fluid at the site of puncture after induction. We do the puncture more readily in the sitting position, although with the patient on the side it is easier and quicker to turn him on his back and place him in the proper position for operation. The head of the table is lowered about 15 degrees. (Pitkin has devised a Tiltometer especially adapted to his method of spinocain induction.) During the operation the blood pressure is recorded every five minutes. If the systolic pressure goes below 60 we give 10 min. of adrenalin hydrochloride (1:1000) intramuscularly; if it drops below 40 or the pulse becomes imperceptible, or shallow respirations are noted, normal saline containing one drop of adrenalin to every 100 c.c. is given intravenously. It is important that this apparatus be always at hand and that if it requires

more than three minutes from the time the order is given to administer it, the technic is unsafe. According to Babcock[1] the brain degenerates and the patient's condition is hopeless if the circulation stops for 7 minutes or more. According to Meeker[6] cessation of heart action is always fatal if it persists a very few minutes. Therefore one can understand the importance of the rapid intravenous injection of normal saline with adrenalin.

We have observed the drop in blood pressure in twenty-five cases and found that in only six was there a drop of 30 points or more in the systolic pressure. Further, this drop occurred in the first five minutes after induction. A 30 point drop in the first five minutes was followed by a further drop in five of the six cases in the succeeding readings at ten and fifteen minutes after induction. In two cases the pressure dropped to zero at the five minute interval and remained so throughout the ten and fifteen minute periods. All of the six cases received adrenalin and four of them were given adrenalin plus intravenous saline. One patient died on the table. This patient was in extremis—a neglected appendix with pneumonia, paralytic ileus, and general peritonitis. He would not allow local, could not stand general anesthesia, and due to distention we could not diagnose the case without the relaxation that spinal induction afforded. I have personally seen three deaths under spinal anesthesia and have recently been told of others. It is well to remember, as I have said before, that if a drop occurs it is sudden and that it is almost always apparent in the first five minutes following induction.

After operation the patient should be moved very gently, never raising the head or body. The foot of the bed should be elevated for the first 24 hours on his return to the room. He should be watched closely for the first hour. Except where the operation itself or the condition of the patient contraindicates it, liquids may be given. Morphine is given for pain.

Postoperative complications were few. In twenty-five consecutive cases paralytic ileus was noted in one; pneumonia in one; immediate headaches in two; headaches after one week in four; vomiting in six cases.

Spinal anesthesia is now being frequently induced at St. Luke's Hospital. Since our first induction on August 6, 1928, until September 14, 1929, it has been used 168 times by eighteen surgeons in operations on the abdomen and lower extremities. In several cases anesthesia was incomplete. Competent observers state that it fails in 1 to 6 per cent of cases (Sise[10]). We have used it successfully in most major operations in the abdomen, pelvis, and on the lower extremities. We do not select it to the exclusion of other anesthetics, using it in approximately one out of every five operations. We rarely use it in upper abdominal surgery. It has a definite field of usefulness, but I believe it should be restricted: (1) to major operations; (2) preferably to those below the umbilicus; (3) to patients physically able to react from the drop in blood pressure.

SOME RECENT ADVANCES IN ENDOCRINOLOGY*

Albert M. Snell, M.D.
Rochester, Minnesota

In the first quarter of this century more discoveries pertaining to the glands of internal secretion have been made than in any other period. Among these may be mentioned the isolation of thyroxine and epinephrine, the discovery of insulin, the isolation of the parathyroid and ovarian hormones, complete revision of knowledge of the pituitary gland, and many notable studies on the suprarenal bodies. Each of these discoveries has stimulated clinical research and has vastly increased both the diagnostic and therapeutic facilities of the physician.

It is my purpose to review here briefly some of the more recent endocrinologic studies and to discuss their clinical applications. The principal reason for such a review is that much of the work concerned is still in the experimental stage and is not generally known to the profession. It may be useful, also, as a sort of antidote to the literature on endocrinology with which some of the unethical pharmaceutical houses have circularized physicians. Perhaps at least 50 per cent of treatment by endocrines as applied today is fundamentally unsound from a scientific standpoint. In spite of rapidly increasing knowledge, this therapeutic field is still limited and can be extended only by painstaking and accurate studies. Understanding of the physiologic and pharmacologic activities of the various hormones recently isolated is of much value in developing conservative and scientifically correct methods of treatment.

PITUITARY GLAND

Among the most interesting studies of the last few years have been those dealing with the pituitary body. This gland has been the object of scientific curiosity since the earliest times. Ancient physicians held the theory that it was an excretory gland for the brain and that certain noxious materials were passed through the gland into the nose or pharynx. Its functions were practically unknown until Marie (1886) described the condition now known as acromegaly, and Minkowski (1887) suggested that this disorder was the result of disease of the pituitary gland. The development of knowledge in regard to the pituitary gland has gone forward steadily since Marie's work. Those interested in the progress are referred to the writings of Biedl, Swale, Vincent, Abel, Geiling and Evans. It suffices to say that the pituitary body is no longer regarded as a single glandular structure, but rather as a group of independent structures which elaborate at least four and possibly more hormones of very different natures and properties.

Physicians are indebted to Herring and his studies in comparative anatomy and embryology for present conceptions of the anatomy of the gland. It consists of four portions: the anterior lobe, glandular in structure and the source of a hormone which has a powerful effect on growth; the intermediate lobe, which invests the posterior portion of the gland and extends up the stalk; the posterior lobe, which is the source of the substance known by the trade name of pituitrin, and another epithelial lobe, the pars tuberalis, which surrounds the infundibulum and spreads out under the floor of the brain. The functions of this last portion of the gland are unknown, but it is undoubtedly of great importance to the organism, since experimental injury to it may be responsible for marked adiposity, disturbances of water metabolism, and so forth. The function of the intermediate lobe is likewise uncertain, although Atwell and Marinus, and others, have suggested that it may be the source of the hormone of the posterior lobe or of some precursor of it. The posterior lobe, according to this theory, may be a place for storage of pituitrin or conversion of these precursor substances.

Anterior lobe.—Only one portion of the pituitary body, the anterior lobe, seems to be essential to life; work on extracts of this portion of the gland has been carried on for some time, and a number of highly contradictory results have been reported. One of the first workers to report significant results was Robertson, who isolated a growth-stimulating substance which he

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the Northern Minnesota Medical Association, Bemidji, Minnesota, September 2 to 3, 1929.

called "tethelin." Since the publication of his work, many other extracts of the anterior lobe have been studied, but only recently has the problem of secretion of the anterior lobe been solved, chiefly through the efforts of Evans and Long. They have been able to prepare an extract of the anterior lobe, which on parenteral injection powerfully stimulates growth. They have obtained marked acceleration of growth in rats by the use of this substance; some of these animals will more than double their weight on this type of treatment. Extracts of this sort also will counteract the changes which appear in tadpoles after removal of the anterior portion of the gland. In their original work, Evans and Long described inhibition of estrum by means of these extracts. It is now known that these earlier results can be explained by the presence of substances other than the growth-stimulating principle. In an article published in 1928 Evans and Simpson claimed to have demonstrated the presence of two hormones of the anterior lobe: one is required for normal growth and development and the other for the development of the gonads, thyroid gland and suprarenal cortex. The effects of the second hormone on the gonads can be practically nullified by simultaneous administration of the substance that effects growth. They suggested that there is very exact adjustment of these hormones in early life in order that growth may be accomplished before the attainment of sexual maturity. They also suggested that the hormone of growth is derived from the eosinophilic cells of the gland and the gonadal stimulant from the basophilic cells.

Putnam, Teel and Benedict have carried this investigation a step further by their work on dogs. They have been able to prepare a pure and more concentrated extract of the bovine anterior lobe, which produces experimental acromegaly in dogs. Their animals gain rapidly in weight when treated with this substance, and definite overgrowth of the bones and viscera takes place. The animals have many of the characteristics of the acromegalic subject; in some, the huge extremities, clumsy gait, and decreased muscular activity are striking. Clinical studies indicate that this extract of the anterior lobe may be of value in the treatment of pituitary insufficiency in the human subject; an attempt to use the substance in the treatment of infantilism is now being made.

Posterior lobe.—The posterior lobe of the gland has long been known to be the source of an extract which is in every-day medical use and which has powerful pharmacodynamic properties. These are so well known that repetition is almost unnecessary. The extract of the posterior lobe, designated pituitrin, has the property of raising blood pressure, as shown first by Oliver and Schäfer, and Howell, of causing a powerful contraction of smooth muscle, particularly that of the uterus, and of having both diuretic and antidiuretic effects. It also affects the chromatic function of amphibians and has the definite property of raising the level of blood sugar. It has been assumed for years that these various properties were each due to individual hormones, although the unitarian theory had also had its strong adherents. The matter appeared to be settled when Abel and his associates,[2] in 1923, prepared from the pituitary gland a highly purified tartrate which possessed all the properties of commercial pituitrin. This salt was one of the most active and potent substances ever isolated; it had oxytocic properties more than 1,500 times as great as an equal quantity of histamine.

Recently, a group of investigators[27] in the laboratory of Parke, Davis and Company has demonstrated that there were two active principles in the posterior lobe. One of these, alpha-hypophamine, possesses the property of causing smooth muscle to contract; the other, beta-hypophamine, contains the pressor and the diuretic and antidiuretic principles. Both of these substances are basic bodies, presumably amines; they may be combined to form a mixture which has all the properties of ordinary pituitrin. These two substances have been prepared under the trade name of "oxytocin" and "vasopressin" and, through the courtesy of the original workers, my colleagues and I have been supplied with material for experimental and clinical study.

Kamm and his associates[27] have found that oxytocin has few properties other than its effect on smooth muscle. At the clinic we have had a similar experience, and have found oxytocin not to have any action on blood pressure, cardiac rate, urinary output or heat production. It causes elevation of the blood sugar when given in large doses, but its effect in this connection is considerably less striking than that of vasopressin, and may be due to the small amount of pressor substance which cannot be completely sep-

arated from the oxytocic fraction. This pressor substance resembles epinephrine in many respects, but on chemical examination it does not give a positive phenol ring test such as is characteristic of epinephrine. The original workers showed that it had a powerful pressor effect, and that in subjects to which it was administered tolerance of pressor activity would develop similar to the tolerance of patients to pituitary preparations. They have also shown that vasopressin contains the diuretic property of pituitary extracts, and also that it has antidiuretic properties. It was found that it has, like epinephrine, the power of raising the level of blood sugar and of partially neutralizing or overcoming the effects of insulin. These effects are not pronounced, and large doses are required to secure them. Unlike epinephrine, it does not exert a calorigenic effect, but rather depresses production of heat. The experiments demonstrating this were performed by Wilhelmj, who believes that the transient drop in metabolism that is observed is best explained on the basis of widespread vasoconstriction. The clinical results obtained with vasopressin and oxytocin are of great interest, but probably the greatest advance which the work of Kamm and his associates represents is along the lines of more exact physiologic knowledge of pituitary activity.

Clinical value of pituitary substances.—The clinical use of these recently isolated pituitary extracts is still in the experimental stage. The growth-stimulating hormone from the anterior lobe which investigators at Harvard are now using, is not as yet sufficiently purified to be available for general use in the human subject. It promises to be of great value in pituitary types of infantilism and in pituitary insufficiency produced by the sugical removal of tumors. Its exact status in the treatment of other pituitary disease is still uncertain. These experimental extracts appear to be the only principles of the anterior lobe which have any clinical value at present. The substance of the anterior lobe which is now sold for oral administration is probably inert, and careful testing of the hypodermic preparations of principles from the anterior lobe, now on the market, has been done with negative results. It is probable that the weight-reducing effects obtained by oral administration of dried substances of the anterior lobe may be due to the presence of certain amines which increase the specific dynamic action of protein foods.[3, 28]

Any further consideration of the therapeutic use of extracts of the posterior lobe is unnecessary because of the wide experience of the medical profession with pituitrin. The advantages

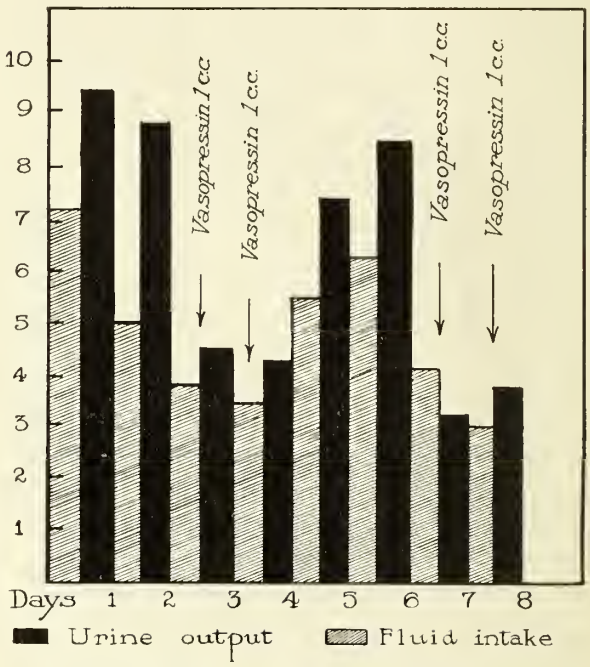

Fig. 1. The effect of vasopressin in diabetes insipidus.

of having the oxytocic and pressor functions in separate preparations is obvious. Oxytocin, or, as it has been renamed, "pitocin," is fully as effective for obstetric use as pituitrin and has the advantage of not elevating the blood pressure.[43] Vasopressin, or "pitressin," is of value for its pressor effects and is extraordinarily efficient in controlling the polyuria of diabetes insipidus (Fig. 1). The pressor principle has some other effects which are of great clinical interest. After operations on the pituitary body, shock may ensue, and there may be abrupt rises in temperature (hypothalamic fever), which cannot be attributed to infection. Vasopressin has been shown by Learmonth to have a definite effect on the abnormalities of heat regulation following operations on the pituitary body. He has demonstrated the beneficial effect of this substance on the blood pressure after such operations. Snell and Rowntree have found it to be of some value as an emergency stimulant in Addison's disease.

METABOLISM OF CALCIUM; THE PARATHYROID GLANDS

The second advance in endocrinology, which I wish to consider, is that which pertains to the regulation of metabolism of calcium. The interest in this field is chiefly due to the recent preparation of active parathyroid extracts which will cause elevation of the calcium of the blood serum. Before commenting on the effects of this extract, a brief statement of the knowledge of metabolism of calcium is necessary. For a more complete account, the reader is referred to Stewart and Percival's recent reviews.[52, 53] An adult requires about 0.4 gm. of calcium a day; a growing child, from three to four times as much. It is absorbed chiefly from the small intestine and is excreted into the colon. Two factors seem to govern the rate of its absorption: the presence of an adequate supply of vitamin D, and gastric acidity. The action of acid can be explained by the fact that it changes organic combinations of calcium into inorganic forms that are more readily absorbed. Calcium probably is excreted chiefly through the bowel, but, because large quantities of calcium pass through the intestinal tract unchanged, the daily rate of excretion is difficult to determine. Soluble forms of calcium are excreted in the urine in amounts of about 0.4 gm. a day in men and in smaller quantities in women. The principal function of calcium is, of course, in the formation of bone, but it is also necessary for the coagulation of blood and for the maintenance of a proper environment for living cells. The relation of the parathyroid glands to metabolism of calcium has only recently been recognized, although the glands were discovered by Sandström in 1880 and the condition of tetany which follows the removal of the parathyroid glands has long been appreciated.

McCallum and Voegtlin (1908 and 1909) demonstrated that after parathyroidectomy the blood calcium was decreased and that intravenous injection of calcium salts relieved the symptoms of tetany thus produced. Fourteen years later, their work was fully corroborated by Salvesen, who stated: "The symptoms of parathyroid insufficiency are due to calcium deficiency. The parathyroids control the calcium level of the blood and by doing so they influence the function not only of the muscles and nerve tissues but probably of all the organs."

Shortly afterward, Hanson, Collip and Berman, working independently, prepared extracts of the parathyroid gland which not only controlled the symptoms of tetany but which were capable of causing elevation of calcium of the blood serum in normal animals. Collip,[11, 12]

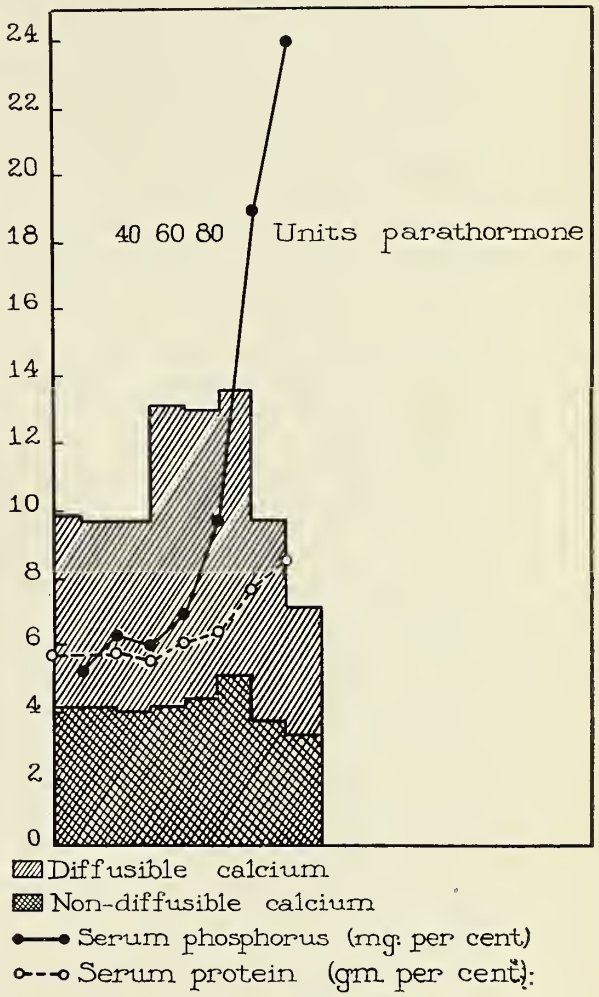

Fig. 2. Hypercalcemia.

whose work overshadows that of other investigators in this field, also demonstrated that if the parathyroid hormone was administered continuously in large doses, the blood calcium could be increased to double the normal amount; if treatment were continued, the blood phosphorus eventually rose and the nitrogenous constituents of the blood were greatly increased; the blood also became greatly concentrated. This condition, which is known as hypercalcemia (Fig. 2), may be fatal unless the use of parathyroid extract is discontinued.

During the administration of the parathyroid

hormone, there is a greatly increased excretion of calcium, which presumably comes directly from the bones. It is theoretically possible to decalcify the skeleton by the use of this substance, and there is no doubt that long-continued use may lead to definite skeletal defects. The best evidence on this point is given by the recent work on hyperparathyroidism. Barr, Bulger, and Dixon recently have described a case of hyperparathyroidism in which a parathyroid adenoma was present. The over-supply of parathyroid hormone thus produced leads to rarefaction of bone, to multiple cystic tumors of bones, muscular weakness, hypotonia, formation of calcium stones in the urinary tract, and abnormally high levels of calcium in the blood and urine. Removal of the parathyroid adenoma in this case, as well as in the cases recently reported by Wilder, and Stearns and Boyd, resulted in reduction of the blood calcium to the normal level, striking decrease in excretion of calcium and great improvement in the condition of the patient.

A word as to the mechanism by which the parathyroid hormone exerts its normal function is perhaps desirable, although the subject is not as yet fully understood. The blood serum is supersaturated with calcium phosphate, and much calcium can be removed from it by shaking with dry calcium phosphate.[23] This supersaturation is brought about by a series of equilibriums between diffusible and nondiffusible forms of calcium. About 50 per cent of the calcium of the blood serum is in combination with the serum proteins and cannot be removed by diffusion. There is also a freely diffusible and ionized portion, probably consisting of inorganic calcium salts. A third portion, nonionized, but diffusible also, exists, and probably represents the portion which is directly influenced by the parathyroid hormone.[9] The presence of a nondiffusible portion of blood calcium obviously explains why calcium does not entirely disappear from the blood after parathyroidectomy and also explains the low blood calcium encountered in nephrosis, kala-azar and other diseases in which there is a deficiency in serum protein. In these diseases, tetany is rare, although the blood calcium will reach the level observed in tetany. This seems to indicate that the diffusible portion of the calcium is that which protects the organism against tetany. There is evidence to show that the diffusible fraction is definitely increased by the administration of parathyroid hormone and that this diffusible portion is decreased after parathyroidectomy.[24] Imperfect experimental methods make this conception somewhat uncertain, although it has been partially confirmed. The function of the parathyroid hormone is probably exerted by its effect on the diffusible calcium, both ionized and nonionized, in the blood stream; in case of deficiency of calcium, more calcium, also diffusible, is drawn from the skeleton by its action. This diffusible portion is, of course, readily capable of elimination by the kidneys and bowel. Vitamin D appears to exert its influence, in part, through the parathyroid glands, since Hess and his collaborators have shown that ergosterol, which normally causes an increase in the blood calcium, does not have this effect after thyroparathyroidectomy.

Clinical applications.—It is obvious that the clinical use of parathormone is confined to two groups of cases: those in which it is desirable to bring about elevation of blood calcium temporarily, for relief of tetany, and those in which it is desirable to withdraw calcium from the body. The use of this extract in parathyroid tetany is well known and need not be considered here. It is also useful in the tetany of pregnancy[11,12] and in tetany associated with the diarrhea of nontropical sprue as Holmes and Starr, and Habein and I have shown. When parathormone is used to correct a condition of low blood calcium, the conjoint use of calcium salts and diets high in calcium and in vitamin D is necessary to prevent skeletal depletion. The use of parathyroid extract as a diuretic has been discussed recently by McCann and Meakins. The effects which are obtained probably are due to two causes: to increased excretion of fixed base (calcium) and to elevation of the serum proteins which may occur.

The use of parathormone as a decalcifying agent probably will receive more attention in the future. Aub and his associates[26] have shown that in chronic lead poisoning, lead is stored chiefly in the bones as the tribasic lead phosphate. They have shown also that any substance which increases the excretion of calcium will also increase the excretion of lead. Therefore, they have used large doses of parathyroid extract in the treatment of this condition, with beneficial results. Hench and I recently attempt-

ed to decalcify a patient who was suffering from chronic infectious arthritis, characterized by extensive deposits of calcium about the joints. The results were gratifying in that the patient lost considerable quantities of calcium and obtained increase in motion in the affected joints (Fig. 3).

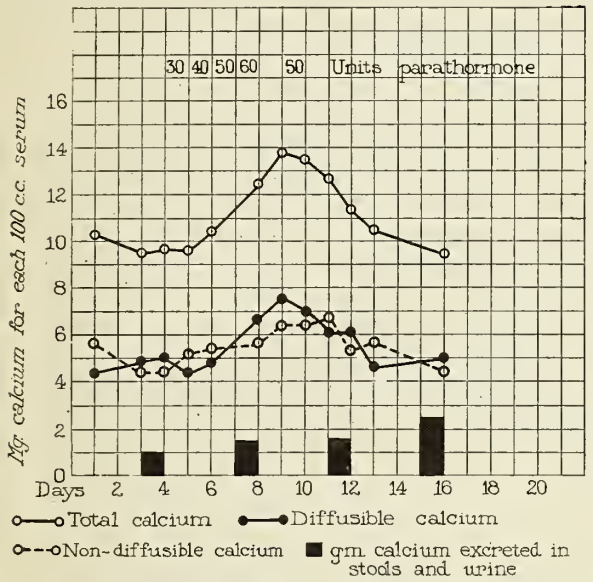

Fig. 3. The effect of parathormone on the calcium of the blood serum and the excretion of calcium in chronic infectious arthritis.

Parathyroid extract has been given by mouth for the treatment of various cutaneous conditions, as well as varicose ulcers, and sprue. The best authorities insist that it is without effect when given in this way, although the blood calcium may be elevated slightly by oral administration of parathyroid extract. Probably, however, the only proper use of parathormone is by hypodermic injections, and even there it is not altogether a safe substance for general use. The danger of hypercalcemia makes it necessary to determine the blood calcium frequently and its long-continued use undoubtedly will lead to skeletal defects. Curiously enough, tolerance to parathormone may be developed; this probably represents the refusal of the bony tissues to give up any more of the calcium which is needed for their integrity.

THE SUPRARENAL GLANDS

A third notable advance in endocrinology has to do with the function of the suprarenal glands. It has long been known that these structures consist of phylogenetically and functionally distinct portions: the cortex which arises from the wolffian body, and the medulla which originates in the embryonic sympathetic system. The secretion of epinephrine, which is a pure medullary product, is not the sole function of the glands. As numerous investigators[8, 13, 24, 55] have shown, the medulla may be removed or destroyed without the slightest effect on the health of an animal, whereas removal of both suprarenal glands is almost uniformly fatal. It seems from this that the cortex is the portion of the gland essential to life, and that the loss of cortical function is responsible for most, if not all, of the symptoms of suprarenal insufficiency. Kovacs reported a case of Addison's disease in which the cortex alone was destroyed; a similar case was recently observed at The Mayo Clinic. The desirability of studying the function of the cortical portion of the gland, and of obtaining an active extract from it, is obvious.

The function of the medullary portion of the gland in the intact animal is uncertain. Cannon expressed the belief that it may supply an emergency stimulant, whereas many other physiologists have thought that it is primarily a substance necessary for the maintenance of normal vascular tonus. The low blood pressure and asthenia of Addison's disease have been attributed, probably wrongly, to the failure of formation of epinephrine. The situation has been well stated by Hogben: "There are sufficient grounds to justify the conclusion that adrenalin is set free into the blood stream; it is neither unlikely nor proven that increased secretion of adrenalin plays a minor part in reënforcing the motor phenomena associated with fright and asphyxia, and there is no reason to believe that in mammals the chromaphil tissue serves a prominent or indispensable function in regulating the normal activities of the organism."

It has been suggested that the suprarenal cortex is necessary for growth and development, that it may neutralize toxic substances, and that it may be necessary for the formation of epinephrine from tryptophane. It has also been suggested that it has to do with the metabolism of lecithin and other lipoids. Alsterberg suggested that there is a close relationship between the secretory activity of cortical cells and the functional activity of the body tissues in general. A number of attempts have been made to prepare an active extract of the cortical tissue of the suprarenal glands; Rogoff and Stewart have

been pioneer workers in this field, and recently have prepared a substance designated as "interrenin" which appears definitely to prolong the life of suprarenalectomized animals. The clinical use of this substance in Addison's disease recently has been reported by them, with results which are somewhat difficult of interpretation, but certainly encouraging. At the clinic recently, observations have been made of a patient under treatment with this extract, who appears to have obtained definite benefit. It is only fair to say that the patients treated with interrenin have not lived longer or have not remained in better condition than certain patients who have been treated by the familiar Muirhead regimen.

The possibility that other active and biologically important substances may be derived from the suprarenal glands is now under consideration. Koehler,[29, 30, 31] of the University of Chicago, rerecently prepared a suprarenal extract which is epinephrine-free and which yet shows definite calorigenic activity. It was felt, at one time, that this substance might be the missing cortical hormone, but in a recent personal communication Koehler stated that this view was probably erroneous. The extract which he has prepared, however, has some very interesting properties. It appears to have a definite effect on metabolism of creatine and creatinine; the excretion of creatinine, which is a feature of many diseases characterized by muscular wasting and asthenia, is almost immediately reduced by the use of this substance. In such cases it is also capable of elevating the metabolic rate, of altering the curve of glucose tolerance, and of reducing the oxygen deficit after exercise. This substance has been used clinically with good effect in syndromes of exhaustion, presumably secondary to suprarenal deficiency. It has produced improvement in some cases of myasthenia gravis and in various forms of muscular dystrophy. There is not, as yet, sufficient evidence to warrant a decision as to whether or not this substance prolongs the lives of suprarenalectomized animals; in three cases diagnosed clinically as Addison's disease, my experience with it was unfavorable. Koehler, however, who has the advantage of a fresh supply, has treated one patient, with apparent benefit. All of the patients with Addison's disease who have been treated with Koehler's extract at the clinic were in a grave condition at the time treatment was started, which may explain their failure to improve. Further clinical studies are being carried out with this extract in a number of institutions in this country and a final report on its physiologic activity and clinical use may be expected shortly. At the present time, however, there is no available substance which will counteract or relieve the symptoms of suprarenal insufficiency.

SUMMARY

From the foregoing paragraphs, it is evident that, although much has been accomplished in the field of endocrinology, even more remains to be done. It does not seem likely that any new developments in the field will open up therapeutic possibilities equivalent to those that attend the use of insulin in diabetes, or of thyroid extract in myxedema. The endocrine structures, the functions and activities of which remain to be solved, seem far too complicated for simple solution.

THE BOVINE THYMUS*

A Brief Description and Histological Study

Adolph M. Hanson, M.D.
Faribault, Minnesota

THE bovine thymus develops from the anterior pouches of the third and fourth branchial clefts, the neck-thymus originating from the third clefts, while the chest or heart-thymus develops from the fourth clefts. The bovine thymus, then, consists of two parts: a neck-thymus, which is broader at the base and smaller proximally, grooved on its inner surface for the trachea; and a heart-thymus, which lies in the mediastinum, smooth on its outer convex surface and concave on the heart side. In young calves these thymus glands weigh as much as 350 gms.

The heart-thymus is the first to retrogress, usually, having degenerated into a fatty mass at the end of two and one-half years, but vestiges of the thymus may remain in this location as long as three years. It seems that retrogressive changes do not begin to manifest themselves in the neck-thymus until the retrogression is complete, or almost complete, in the heart-thymus. Early retrogressive changes occur in the neck-thymus in the third year.

The neck-thymus persists in cattle up to twenty years, or longer. It persists longer in beef cattle than in dairy cattle.

The thymus is made up of cells of entodermal, ectodermal and mesodermal origin. Authorities differ as to the exact origin of the various cells found in the thymus and the matter is still under discussion. The histological structure is very much like that of the human gland, with the exception of Hassals' corpuscles, which are rarely seen, and the character of the giant cells in regard to the nucleus.

The bovine thymus in general resembles the same lobulated structure as that of the human gland. There is a more densely cellular dark-staining cortex, with a lighter central area, or medulla, less rich in cells. The cortex is made up of densely packed lymphoid cells and relatively few widely scattered giant epithelial cells. The medulla contains less lymphoid cells with relatively more giant epithelial cells than are found in the cortex. These large epithelial cells are mononuclear in contradistinction to these same cells in the human thymus, which are polynuclear. The nuclei are large and contain coarse granules which appear as long broken strands of a reticular-like network.

Fig. 1. A schematic illustration showing the origin of the thymus bodies from the third and fourth branchial clefts anteriorly. The superior and inferior parathyroids are illustrated as originating from the posterior pouches of the same clefts.

The nucleus is often situated at the side of the cell, and occasionally at, or about, the center. There is a relatively large amount of cytoplasm. These giant epithelial cells are stained faintly by eosin, with the exception of the periphery of, and the granules of, the large nuclei, which take a faint basic stain in contradistinction to the lymphoid cells, the nuclei of which stain deeply with hematoxylin.

These giant epithelial cells are more numerous in the neck-thymus than in the heart-thymus. The epithelial cells of the bovine thymus are peculiar to the thymus as the giant epithelial cells already described. However, the epithelial cells are found to be of varying sizes. The small ones have a large nucleus, larger than that of the lymphoid cells, with a relatively small amount of cytoplasm. The

*From the Chemical Research Laboratory, Faribault, Minnesota.

nucleus is more easily made out than that of the giant cell because it takes a slightly darker stain and the cytoplasm stains more distinctly with eosin. There are varying sizes of these cells from that of the small epithelial cell to that of the giant epithelial cell. The nucleus

Fig. 2. A photograph of the thymus of a young calf showing its relation to the trachea and heart. The lungs are laid back to expose the heart-thymus completely.

increases somewhat in size, but the notable characteristic of the giant cell is its relatively large amount of cytoplasm. It seems that these epithelial cells are various stages in the development of the giant epithelial cell, as they all exhibit the same staining qualities and general appearance of both the nucleus and the cytoplasm.

In addition to the lymphoid cells, there are cells with nuclei larger than the lymphoid cells, but with a very small amount of cytoplasm. Such a cell has been described in the human as being the result of the mitosis of the large epithelial cell. If this is true, it must serve the same function and, perhaps, in its turn attains to the giant size. The giant epithelial cells are essentially acid-staining, while the lymphoid cells take a basic stain.

Evidently there are two distinct and different substances in the thymus. The large number of lymphoid cells may carry on the function common to similar cells in the lymphatic system. It is well known that the blood of children before puberty contains a higher percentage of lymphocytes than that of adults. The giant cells, on the other hand, may be responsible for the secretion of a hormone peculiar to the thymus and, therefore, found in no other gland.

A precipitate obtained by glacial acetic acid from a saline extract of neck-thymus is a smooth paste of a delicate pink color like that of a beautiful pearl, while a similar precipitate of heart-thymus yields a white smooth paste, without any suggestion of a pink color. Is this due in any way to a greater preponderance of giant epithelial secretion?

The existence of a relatively large number of giant epithelial cells in the neck-thymus and the fact that the neck-thymus develops from the third branchial pouch (which seems to be the usual and main source of the thymus in the dog and the human where it is found in the chest and is called thoracic thymus) may be significant.

The first apparent changes in the beginning retrogression of the bovine thymus is a deposit of fat in the stroma between the lobules, which gradually increases as the lobules begin to shrink, so that in older cattle of eight to twenty years of age, the lobules appear as more and more widely scattered isolated islands, which become smaller and smaller. There is a marked diminution of the lymphoid elements, the cells and nuclei becoming smaller, though the giant cells remain in relatively larger numbers. This is not due to an increase in the number of the giant epithelial cells, but to the more rapid disappearance of the lymphoid cells. These giant cells at twenty years of age also show degenerative change to a marked degree. They lose their staining qualities. The nuclei become irregular in shape. The granules of the chromoplasm of the nucleus disappear and the entire nucleus takes on a faint basic stain as though these darker granules had gone into solution. The outline of the nucleus finally breaks down so that only the faintly staining cytoplasm of the cell remains. The color is a barely perceptible light pink under the oil immersion. In other places in the sections studied, simply spaces that were occupied by these giant

epithelial cells are found. Sections of an older bovine thymus require more eosin and less hemalum to bring them out. It is difficult to see the giant epithelial cells, even in sections from young calves, so as to make out their

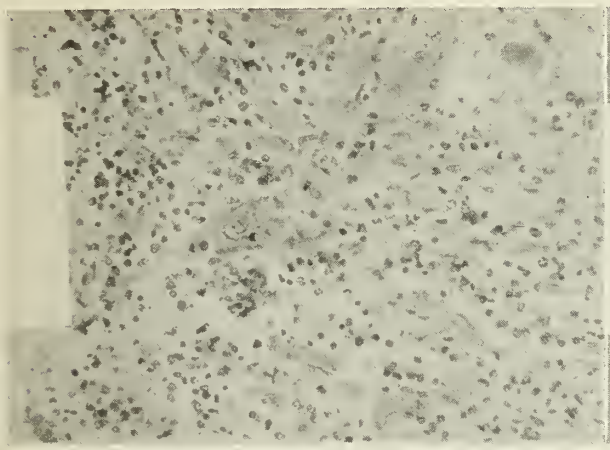

Fig. 3. High power microphotograph showing the giant epithelial cell of the bovine thymus. The large cell near the center shows the character of the nucleus.

definite appearance as they are faintly staining and well camouflaged among the lymphoid elements. Studies of the giant epithelial cells were made under the oil immersion.

This study has led me to suspect that, if the thymus gland has an internal secretion, or hormone, peculiar to itself, it is contained in this giant epithelial cell which is the true thymus.

Very little is known concerning the chemistry of the thymus. Several facts are of interest. Adenine is the predominant purine body, though guanine is also found. While the cells of this gland are very rich in nuclein bodies, they are relatively poor in proteins. Bang has shown that the thymus contains about the same amount of nucleoprotein, but about five times as much histone nucleate as the lymphatic glands. In other words—chemically the lypmh gland and the thymus have this in common: they both contain histone nucleate in large amounts. It can be precipitated from watery, also from weak alkaline extracts, by acetic acid. Extracts containing the lymphoid elements are rich in histone nucleate.

As far as the writer has been able to determine, all thymic extracts used, heretofore, in experimental work have been such extracts.

Arginase, guanase, adenase, and a proteolytic enzyme are found in the thymus. The proteolytic enzyme studied by Jones is interesting in that, contrary to trypsin, it acts best in acid liquids. It is readily destroyed by alkalies at body temperature.

As it is already known that the serum of the noncancerous has a far greater influence in retarding cancerous growth than that of the cancerous, and that of young infants about twenty-one times as powerful an influence in this direction, according to Engel, as that of the non-cancerous adult, it has already been suggested by some that this is thought to be due to the influence of the thymus as it is the only gland that shows marked retrogressive changes with advancing age. The only possible exception to this last statement is the posterior hypophysis, or pineal body.

With the idea that the internal secretion of the true thymus is locked up in the giant epithelial cells and on the supposition that this thymic internal secretion preserves normal epithelial health throughout the entire body, i. e., that it controls and keeps up normal epithelial growth and cell-repair, the writer set himself the task of isolating the true thymic hormone. In order to do this it seemed that a method of extraction that would break down the gland completely and that would exclude the lymphoid elements held out the best hope of solution. For this reason, the

writer has employed an original method that differs from all other known methods, which has resulted in the production of a clear extract with a protein content of about 2 per cent. This extract contains no histone nucleate. It is called Karkinolysin, because it

seems to have a solvent action in carcinoma when injected intramuscularly daily over a period of months in highly malignant types and with as few as twenty injections in types of slower growth.

ACKNOWLEDGMENTS

I am indebted to W. S. Nickerson, M.D., Sc.D., for the preparation of the tissue sections of bovine thymi, ranging in age from two weeks to twenty years of age; to Swift & Company and their Mr. C. P. Kaufmann for the bovine thymi sent me from their plant in South St. Paul; to E. O. Ellingson, Ph.D., Professor of Chemistry at St. Olaf College, Northfield, Minnesota, for Kjeldahl checks to accurately determine the protein content of various lots of Karkinolysin; and to Dr. F. R. Huxley for his kindly interest and encouragement, and for his help in reviewing this article before publication.

IODIZED OIL FOR DISEASES OF THE CHEST*

Everett K. Geer, M.D.
Saint Paul

VARIOUS attempts have been made in the past twenty-five years to find some non-irritating substance opaque to the *x*-ray for visualizing the bronchial tree. Bismuth oxide and subcarbonate insufflations, iodoform emulsion in olive oil, anhydrous thorium oxydate insufflation, bismuth subcarbonate suspended in olive oil have all been tried and in the main abandoned. Iodized oil on the contrary has been accepted universally since Sicard and Forestier made their first report in 1922. Since then it has attained a position in the diagnosis of diseases of the chest that is comparable in no small degree to the use of the barium meal in gastro-intestinal investigation or to sodium iodide solution for urologic examination.

In non-tuberculous diseases of the chest, the outstanding fact which the intra-tracheal use of iodized oil has made clear is that ectasis of the bronchi occurs much more commonly than believed heretofore. It is well, of course, to keep in mind the picture of the advanced bronchiectatic with cough of many years duration, with abundant, purulent, and frequently malodorous sputum, with the indefinite physical and *x*-ray findings, with the clubbed fingers, etc. But it is much more important to remember that bronchiectasis may not be advanced, that it may be not only early but dry. Iodized oil has taught us these two valuable lessons.

Furthermore, its use not only leads to a more exact diagnosis in a qualitative sense but gives a very precise idea as to how extensive any given bronchial dilatation may be and where it is located. These factors must be known definitely before any treatment can be instituted rationally.

Rules in medicine are dangerous by and large but I venture this one: That in all cases of chronic cough, dry or productive, where tuberculosis, heart disease, lung or pleural abscess and accessory nasal sinus disease (many people with chronic sinusitis have an associated bronchiectasis) can be ruled out, the injection of iodized oil is indicated to prove or disprove bronchial dilatation.

With lung abscess it is highly desirable to localize definitely the cavity or cavities, particularly if open drainage is anticipated. Here, intra-tracheal iodized oil may help, but in the majority of cases it will not. A number of factors are responsible for this failure. There may be a marked bronchial stenosis proximal to the abscess, a very common finding with lung abscess and one of the reasons which has made bronchoscopic drainage of this condition a very wise procedure; or the bronchial opening into the abscess may be so situated (the superior wall, for instance) that the oil cannot enter; or the size of the opening may be too small to permit the oil to pass, or there may be a plug of mucus or pus blocking the way or the cavity may be filled with exudate.

At times it may be desirable to outline clearly localized empyema cavities before operation. Iodized oil injected directly into the cavity does this decisively and especially so if *x*-ray films are made with the patient in various positions. Or again in certain obscure conditions intra-tracheal oil may reveal a partially stenosed bronchus which will lead to bronchoscopy and a more definite diagnosis. In outlining tracheo- or broncho-esophageal fistulas, iodized oil is preferable to barium because of its blandness.

In tuberculous diseases of the chest iodized oil should be used with discrimination. Some men contend that the presence of pulmonary tuberculosis is a contra-indication to the introduction of iodized oil into the tracheo-bronchial tree. I cannot agree with this restricted attitude. Others feel that acutely active lung tuberculosis militates against the use of the oil and with this view I concur heartily.

I have used iodized oil in tuberculous patients or suspects for two main purposes:

(1) For study of unexplained hemoptysis.

(2) For further investigation of unsuccessful thoracoplasty.

In studying persons with unexplained hemop-

*Read before the Ramsey County Medical Society March 25, 1929, and the Southern Minnesota Medical Association June 15, 1929.

tysis, iodized oil has been utilized with early or dry bronchiectasis in mind. It is taught today that ninety-five per cent of unexplained hemoptyses is due to pulmonary tuberculosis. I doubt this. There can be no doubt that there is a tuberculous basis for a high percentage of these hemorrhages, but I am convinced by experience that some of the ninety-five per cent are bronchiectatics. It is being appreciated more generally that bronchiectasis is a frequent cause of hemoptysis which at times is profuse. The judicious use of iodized oil will save many persons in this group of unexplained hemoptyses an unwarranted diagnosis of pulmonary tuberculosis.

In any group of thoracoplasty cases there will always be a number who continue to cough and raise sputum, which may or may not contain tubercle bacilli, in the face of what appears to be a good collapse. Physical examination in most of these people tells no more than was known before. Stereoscopic films of the chest may not be helpful because of extensive fibrosis, thickened pleura, or both. Despite the more or less empirical warnings in the literature, I began using intra-tracheal oil in a few selected thoracoplasty patients who had not exhibited reasonable improvement. Nothing eventful happened and the oil did disclose the reasons for failure. It was found that unsuspected bronchiectasis, unclosed cavities, or both, were the main causes of unsuccessful thoracoplasty. These findings, which were consistently present in subsequent cases, led to routine phrenic nerve avulsion, preliminary to thoracoplasty, and to more extensive rib resections.

Iglauer and Kuhn[2] feel that brominized oil is more suitable for tuberculous patients. The technic necessary is not as simple as with iodized oil and they admit that the shadow cast by brominized oil is not as dense. I have followed some forty tuberculous patients at Pokegama Sanatorium and at the Ancker Hospital Tuberculosis Pavilion who have had iodized oil injected intratracheally, and I see no reason for discontinuing its use, providing the tuberculous lesions are chronic and other contraindications absent.

There are five methods for introducing the oil into the tracheo-bronchial tree: (1) supraglottic; (2) transglottic; (3) subglottic; (4) passive; and (5) bronchoscopic. I have used the supraglottic route exclusively in over two hundred injections and have found it quite satisfactory. Any portion of the bronchial tree can be reached by altering the position of the patient, as the oil is heavy and gravitates readily.

Smyth and Schall[6] make a strong plea for the bronchoscopic method, believing that a thorough cleaning of the bronchial tree is essential before the oil is injected. I have not found this to be so and further feel strongly that a person with lung tuberculosis should not be submitted to bronchoscopy except for emergencies. Ochsner[3] favors the passive method; Pritchard[4] the supraglottic. In small children either the subglottic (puncturing the crico-thyroid membrane) or the bronchoscopic method must be used for obvious reasons. The youngest patient I have injected was eleven years old and no difficulty was encountered with the supraglottic method.

The possible complications from attempting to inject iodized oil into the tracheo-bronchial tree are:

1. Acute enteritis. This results from swallowing the oil, with subsequent liberation of free iodine by the action of the alkaline intestinal secretions. This has not occurred in any of my cases although some have managed to get oil in the stomach.

2. Iodism. This may result from swallowing oil or may occur because of an idiosyncrasy. This also is uncommon. It has happened only once in a mild form in my experience.

3. Aspiration pneumonia and lighting up of old tuberculous foci are two other possible complications but I have seen neither of them.

The two most important contraindications to the use of iodized oil intra-tracheally are:

1. Acute or recent upper respiratory infection.

2. Acutely active tuberculosis of the lungs.

It is well also to refrain from using the oil in any condition in which freedom from even mild strain is imperative.

The ultimate disposition of iodized oil after it has entered the tracheo-bronchial tree and lung parenchyma is interesting. The iodine is liberated so slowly that it does not irritate and is eliminated in the urine. The oil in the pulmonary alveoli, according to Brown,[1] is taken up by phagocytes apparently of endothelial origin which follow on into the lymphatic system. It is questionable whether direct absorption or digestion of the oil occurs. A certain amount of the

oil is eliminated by expectoration. Some people will retain for months enough oil in their lungs to cast a shadow on an *x*-ray film with no demonstrable ill-effects.

The potential therapeutic action of iodized oil has held forth enticing possibilities because of its iodine content. Many men have been impressed by its action on bronchiectasis. I have given series of injections to ten persons with bronchiectasis. Six had enough reduction in cough and sputum to have returned asking for more oil. Three showed no improvement. In one instance only have I been able to render a patient with definite bronchiectasis, cough- and sputum-free. Pritchard thinks that if used repeatedly (twelve to sixteen injections at weekly intervals) iodized oil produces fibrotic changes in the bronchial wall and surrounding lung parenchyma with subsequent shrinking and in early cases of obliteration of the dilations. This has not occurred in any of my cases.

Ransohoff and Heiman[5] have called attention to the beneficial action of iodized oil in treating empyema and reported four acute cases and one chronic which healed promptly after its use.

It seems, therefore, that iodized oil has some curative value. In the main, however, it will remain a diagnostic agent in diseases of the chest as in other fields, with any reputation for healing occupying a position of secondary importance.

THE VALUE OF THE *X*-RAY EXAMINATION IN PULMONARY TUBERCULOSIS*

Leo G. Rigler, M.D.
Minneapolis

THE importance of the *X*-ray examination in the diagnosis and study of pulmonary lesions, especially tuberculosis, is well known. The amount and character of the information obtained by this method is not so clearly understood. In order to be able to appraise the results of an *x*-ray examination, the limitations, possibilities, and factors of error in the method must be defined.

The technic of the *x*-ray examination of the lungs is of the first importance. Fluoroscopic examination is of little value in the diagnosis of early or minimal tuberculosis. In the later stages, gross lesions may be recognized and much information may be gained in particular cases, but on the whole the results of fluoroscopy are neither accurate nor dependable. Films of the lungs must be made, preferably stereoscopic, the latter being of especial importance in the diagnosis of the early case. The films must be technically almost perfect. In order to achieve this it is necessary to have a powerful *x*-ray transformer capable of sufficient energy to make very rapid films. Intensifying screens must be fast, flawless, and much have good contact with cassettes. This necessitates frequent changing of both screens and cassettes. A fine focus tube must be used and the films must be made without movement or breathing on the part of the patient.

It is dangerously easy to obtain findings simulating early tuberculosis or to obliterate the signs of an early tuberculosis as a result of poor technic. Most of the errors which we observe, however, are on the side of overinterpretation rather than underinterpretation. It must be borne in mind that the roentgen diagnosis of tuberculosis is considered to be a very certain one; a patient should never be stigmatized with it without adequate evidence. It is a frequent experience to see a diagnosis of pulmonary tuberculosis made from the *x*-ray examination because of coarsening of the normal broncho-vascular markings in the lung. This may be due entirely to a broad focus tube, or to lack of speed. On the other hand, if fine detail is lacking in the film of the chest, minimal tuberculosis may be easily overlooked.

If we assume that the *x*-ray technic is good, what can we determine from the roentgen examination of the lungs in a patient suspected of tuberculosis? The first consideration is whether there are any abnormal changes in the lungs. The symptoms of tuberculosis may be simulated by a host of other conditions. Tuberculosis may exist in the body elsewhere than in the lungs and give the same systemic symptoms. The roentgenogram presents a fairly accurate picture of the pathology in the lungs; in many cases almost as accurate, when properly interpreted, as a gross pathological examination. The absence of any abnormal changes is the best, the most conclusive, evidence against pulmonary tuberculosis that we now have. It can be stated that, in the presence of symptoms due to tuberculosis of the lungs, some *x*-ray signs will almost always be present if an adequate examination has been made. With only one or two exceptions, I have never seen a case presenting symptoms of tuberculosis and which eventually proved to really have pulmonary tuberculosis in which the *x*-ray examination was negative. In the absence of *x*-ray signs, therefore, the presumption is overwhelmingly against the diagnosis of tuberculosis in the lungs.

On the other hand, it is often astonishing to find extensive changes in the roentgenogram of the lungs which were unsuspected even after careful examination by experienced clinicians. This occurs sufficiently often to point out the necessity for roentgen examination in every case suspected of pulmonary tuberculosis. Even if the physical examination is entirely negative, no patient presenting symptoms suggestive of tuberculosis should be allowed to go without an adequate *x*-ray examination of the lungs. In most cases the *x*-ray signs are present before the physical signs become apparent. The presence of typical roentgen findings is positive evidence of pulmonary tuberculosis second only in certainty to the finding of tubercle bacilli in the sputum.

*From the Department of Roentgenology of the University of Minnesota and the University Hospital, Minneapolis.

It should be noted, however, that not infrequently abnormal changes are present which are not typical. Under these circumstances the *x*-ray examination merely indicates the presence of pathology; the clinical examination must determine whether it is tuberculous or otherwise. Usually the coördination of symptoms, physical signs and *x*-ray findings will determine the diagnosis definitely. Frequently it is necessary to reexamine at an interval of one or two months to rule out the possibility that the lesion which has been observed was due to some acute condition. Cases of atypical bronchopneumonia, especially those secondary to influenza, pulmonary congestion, acute bronchitis, chronic bronchitis and bronchiectasis, chronic or unresolved pneumonia, and chronic lung fibrosis, may be difficult to differentiate at times; the clinical findings in some cases and reexamination with the *x*-ray in others will usually indicate the correct diagnosis.

Shadows in the lung fields characteristic of tuberculosis do not, however, necessarily mean active tuberculosis. This is exceedingly important because such a large percentage of apparently normal individuals have healed lesions which may give more marked *x*-ray findings than a recent active infection. For example, changes in and about the lung roots in adults are very commonly present and, in themselves, are usually of no importance. Fibroid lesions in the apex, pleural thickenings, and calcifications in the lung fields are very frequently seen but in most cases they have no clinical significance. All other types of shadows usually have a more important bearing on the immediate condition of the patient but the actual activity cannot always be determined with any great certainty by the *x*-ray examination. It is true that in some cases the sharpness, density, and discreteness of the shadow may clearly indicate a healed or quiescent lesion. In others a hazy, radiating, not sharply demarcated, soft-looking shadow may determine definitely that the disease is active. In general, however, the activity or quiescence of the disease should be determined by the symptoms and physical signs.

The diagnosis of tuberculosis having been established, much more information may be had from the roentgen examination and here again the accuracy of this method is of great value. We can determine the extent of the lesion, whether it involves more than one lobe, or more than one lung. The demonstration of the complete freedom of one lung from disease is obviously of the greatest value as an indication of whether or not surgical procedures should be used for therapy. The extent of the lesion will to a large extent determine the prognosis.

The character of the tuberculosis present may also be made out in this way. In general, pulmonary lesions may be classified as exudative or proliferative, although in most cases both types are present. The proliferative lesions tend to give rather sharp, fibrotic-looking dense bands, or moderately discrete, fairly dense nodules. The exudative types are more likely to be hazy, feathery, not sharply outlined, very irregular masses. Usually the latter indicate a very active, somewhat malignant, rapidly progressing process. On the other hand, if cure takes place, the exudative type of lesion will show the least amount of scar and residue. It is often astonishing to see the complete disappearance of what appeared originally to be a far-advanced tuberculosis. Much of the shadow seen in this type of case is really due to secondary collateral inflammation in the lung rather than to actual tuberculous infiltration.

The presence of cavities, of course, modifies the outlook in any case of pulmonary tuberculosis. Their presence can be most easily detected by *x*-ray examination. Acute miliary tuberculosis within a week after its onset usually gives definite *x*-ray findings and a definite diagnosis may thus be made very early. Tuberculous pneumonia, pleural thickenings and pleural effusions, spontaneous pneumothorax, can be accurately delineated often long before the symptoms or physical signs make the diagnosis possible.

Finally, there is no better method for observation of the patient with pulmonary tuberculosis than serial roentgenograms. These give an accurate history of the pathological events which are taking place in the lungs. The extension of the tuberculous process to a lower level in one lung or to the other lung, the appearance of a cavity, the development of a bronchogenic dissemination or of a miliary spread, all can be clearly demonstrated if *x*-ray films are made at suitable intervals with a reasonably constant technic. On the other hand, the gradual progress of an active exudative lesion into a quiescent proliferative one can be readily observed. The appearance of fibrotic bands, pleural adhesions, retraction of the trachea, mediastinum and diaphragm, and the

deposition of calcium in the lung fields and mediastinal lymph nodes—all the evidences of a healing process—can be clearly discerned in this manner.

During the course of collapse therapy the roentgen examination is invaluable. The amount of pneumothorax, the degree of lung collapse, the onset of complicating pleural effusion, the position of the diaphragm after phrenic exuresis, and the position of the bony thorax after thoracoplasty, can all be best observed by fluoroscopic and repeated film examinations.

It is outside the scope of this paper to discuss the actual diagnostic criteria of pulmonary tuberculosis in the roentgenogram. I must reiterate that most of the errors lie in overinterpretation of normal findings. This is particularly true of the vascular markings in the lungs which under various conditions may be accentuated. It must be borne in mind that the first and only pathognomonic lesions of tuberculosis are the tubercles. These are in the parenchyma of the lung and tend to give nodular areas of density or a veil-like shadow near the periphery. They do not follow the vascular tree in any organized form and varying accentuations of the latter are usually of little significance in the diagnosis of pulmonary tuberculosis.

SUMMARY

1. Technical factors in the roentgen examination of the lung for tuberculosis are of great importance. Fluoroscopy is of little value in the diagnosis of early cases and stereoscopic films of the highest quality are imperative.

2. A negative *x*-ray examination is the best evidence against pulmonary tuberculosis that we have. In the presence of symptoms due to tuberculosis in the lungs the *x*-ray examination is almost always positive.

3. Every patient with symptoms suggestive of pulmonary tuberculosis should have an adequate *x*-ray examination regardless of a negative physical examination.

4. Next to a positive sputum, characteristic *x*-ray findings are the most positive evidence of pulmonary tuberculosis.

5. The *x*-ray findings frequently do not indicate whether the tuberculous lesion is active. This may be better determined by the clinical findings.

6. The roentgen examination gives an accurate picture of the extent and type of the tuberculous lesion which is present. It is an invaluable aid in determining the type of therapy to be used, the effects of therapy and to follow the progress of the disease.

THE MANAGEMENT OF TUBERCULOSIS*

H. A. Burns, M.D.
Superintendent, State Sanatorium
Ah-Gwah-Ching, Minnesota

"When we consider the transcendent importance to the human race of the observations of Koch on the etiology of tuberculosis, and the completeness of his demonstration of the communicable and preventable character of the disease, it seems difficult to understand the limited extent of the sanitary procedures since adopted for its restriction. The imperative demand for the enforcement of comprehensive measures for the prevention of tuberculosis should have been as evident to sanitarians twenty years ago as it is today."

—Herman M. Biggs, 1904.

TWENTY-FIVE years have passed since Dr. Biggs made this statement. Koch is credited with the prophecy that "not until a younger generation has appeared which has had a different scientific training, and holds views more in harmony with the known facts regarding the etiology of tuberculosis, will it be possible, in my opinion, to bring about an intelligent supervision of the disease." With both retrospect and prophecy before us, let us evaluate the accomplishments which have been made in the management of tuberculosis.

The attitude of the profession towards tuberculosis in the past was one of interest in a continuous study of pathology from the time of diagnosis to the time of death. The patient contributed his part by remaining immobilized for weeks and months, optimistic and hoping for recovery, while the doctor separated himself from the patient by an impassable gap, waiting for death.

The management of tuberculosis has become a specialized problem in medical administration. Many difficulties have been overcome. Many advantages have been recognized and accepted. Sir Edward Newsholme has concluded, after making an exhaustive study of the results of isolation in tuberculosis control, that, "If you will isolate twenty per cent of the open cases of tuberculosis in any community for a period of four months each year, the death rate from the disease will show in that community a yearly decrease of two per cent. Since 1900 the sanatoria in the United States have increased from 42 to 700, while the beds for cases of tuberculosis have increased from 3,600 to 73,000.

As facilities have been provided for the care of the tuberculous, a marked reduction in the death rate confirming Newsholme's conclusions has occurred. In 1900 the death rate was 202 per 100,000 population, while in 1926 the death rate had fallen to approximately 87 per 100,000 population.

The sanatorium has evolved from a primitive institution to one that meets the requirements of modern treatment. Dr. David R. Lyman has said, "Our first idea of a sanatorium was a porch, a reclining chair, a rule book, three quarts of milk and six eggs a day, and a chest examination once a month. In those days a sanatorium was usually conducted by a sick doctor who had been hired principally because of the fact that he was cheap. We have found out that tuberculosis work, whether in the sanatorium or hospital, requires as high a grade of medical service as that of the most modern general hospital."

The sanatorium, from this primitive conception, has gradually become a socially-minded institution, and as a result it has extended its activities into the community it serves. The tuberculosis field nurse has become an adjunct to the sanatorium whose value can not be overestimated. The medical staff are health officials doing in their sanatoria epidemiological work of great value and importance. The sanatorium has become the center for many health activities in tuberculosis work. It has changed so much in construction, administration, equipment and service, that it does not differ materially from the general hospital. This change has been brought about so quietly and so completely that the first recognition of the fact has come through the demand for the use of tuberculosis beds in general hospitals. The acceptance of such cases in general hospitals is a compliment to the sanatorium. They meet on common ground for a single purpose. The fact that most communities are served by general hospitals, and that comparatively few are served by sanatoria, makes it possible to

*Presented at the Tuberculosis Institute, Ah-Gwah-Ching, Minnesota, May 2, 1929, and under the General Extension Division, University of Minnesota, June 24, 1929.

promptly isolate open cases by the use of these additional beds in general hospitals. The immediate use of general hospital beds in the community reduces prolonged exposure at home while remaining on the waiting list for admittance to either a local or distant sanatorium. The open case in the general hospital is possibly of greatest value for the training it gives to doctors, nurses and attendants in preventive methods. It results in the popularization of sanatorium teachings and practice throughout the entire medical and nursing professions. It is true that tuberculous patients offer a risk to both hospital personnel and to the other patients; so also do pneumonia, typhoid fever, influenza, syphilis, and dysentery cases constitute a risk to those not infected. The problem is in the early recognition of the possible danger in each type of disease and sterilizing the infected discharges before they are permitted to enter an environment that eventually leads to contact with another human being. The danger of contact tuberculosis infection does not lie in the fact that a known open case is housed next to a susceptible person, but that many unknown cases are carelessly establishing such contact. The opening of general hospital beds will increase many times our capacity for the prompt hospitalization of cases, and the training given will result in a tremendous advantage to our future anti-tuberculosis work. The sanatorium can no longer be considered other than a specialized hospital. It teaches its patients the value of routine and self-discipline. Its patients hospitalized for long periods of time have many intercurrent disabilities which demand immediate and expert attention. The sanatorium takes an active interest not only in the convalescence of its sick, and their eventual discharge, but also their social and industrial re-establishment. The use of general hospital beds for tuberculosis cases will add more treatment beds than can be acquired through any sanatorium construction program. Prophylactic technic will become a procedure in common use throughout all hospitals. This change in the physician's attitude towards the care of tuberculosis will bring about a saner appreciation of the problem as a whole throughout all classes of society. The sanatorium has become, and promises to become even more, a community health center where health habits and health discipline are major activities.

The management of tuberculosis, the study of its prevalence as well as the many phases of its epidemiology, cannot be made a part of our future plans of offensive warfare without the aid of carefully and daily compiled records. The newly admitted patient must have records, and these records must be studied individually and collectively. The end-results of such data and study will be a check upon the efficiency in terms of service which the sanatorium renders the community it serves.

The successful management of tuberculosis depends largely upon the accurate interpretation of its epidemiology. Much of the data invaluable to the epidemiologist can be gotten only in the sanatorium. Good institutional administration must have such data recorded and accumulated for this study. It is, therefore, essential that complete coöperation exist between the leaders along the entire offensive front. It is problematical whether it is good tuberculosis control (surely it cannot be considered good logic) to include in the preventorium parenchymal and juvenile types of the disease. The tuberculosis school of the Lymanhurst type has proven itself more economical and epidemiologically safer than the preventorium which houses mixed types or permits association with adult cases. So far as the management of tuberculosis is concerned, the school, the preventorium, the sanatorium and the clinic are each an instrument of its epidemiology. In order that these instruments may be manipulated to the greatest advantage in tuberculosis control, some central control of the problem must be developed and maintained.

Since the discovery of the tubercle bacillus in 1882 by Koch, the most outstanding improvement added to the treatment of tuberculosis is the acceptance of surgery by the tuberculosis specialist as a routine mode of treatment. This has not only aided in the recovery of individual cases, but has radically altered our conception of the management of the disease. In the past, laws were frequently enacted providing that one sanatorium should care for early treatable cases, while another was designed for far advanced cases only. Surgery has upset the feasibility of any such arrangement. Many cases rated under this interpretation of legal enactment as far advanced would remain indefinitely for domiciliary care. With the aid of surgery, spectacular recoveries have been effected. With the possibility of surgical interference, all cases of pulmonary tuberculosis must be considered as treatable until the terminal stage has been reached. This radi-

cal change introduced into the therapy of tuberculosis has revolutionized its management from the patient's as well as the physician's point of view.

The point of breakdown is always a landmark in the history of each case of pulmonary tuberculosis. At this point toxemia overcomes resistance, making it difficult or impossible for the patient to carry on. Prior to and leading up to this event the patient gives rather accurately a history of a train of symptoms beginning from a fairly well identified incident or date which leads to the third milestone in the development of clinical tuberculosis—the end-results of a series of accidents which began with the initial infection followed by the onset of definite and continuous prodromal symptoms eventually bringing the patient to the point of breakdown. The prodromal period in pulmonary tuberculosis is as characteristic of this disease as is the prodromal period of typhoid, measles, smallpox or lobar pneumonia. Frequently the infection does not progress far before the individual wins the battle and the prodromal symptoms are aborted or controlled. Most frequently the infection does not progress sufficiently to usher the individual through or even into the prodromal stage. It is a very small minority group of those originally infected that ultimately reach the point of breakdown. Yet it is this relatively small group that make tuberculosis the problem that it is. The biology of the tubercle bacillus is such that it must depend upon this small but selected group of human beings to live and propagate. The most successful warfare against tuberculosis is that carried on before the infected body has been converted into a host. To give the patient the greatest benefit of treatment the disease must be identified while still in the prodromal stage.

The patient knows rather accurately the circumstances surrounding the onset of prodromals that have led up to the point of breakdown. Cases that become far advanced through progressive infiltration do so quickly following the initial breakdown or subsequent periods of reactivation. If medical science is to aid the tuberculous it must be given early through focusing its energy upon the identification of the disease before the point of breakdown has been reached. Identifying the early case becomes of importance only if hospitalization can be immediately secured and treatment initiated. The initial infiltration is frequently the only one. This may be either minimum or extensive so far as area involved is concerned. Spreads from the initial lesion, while frequently observed, are relatively rare. The far advanced case and the minimum case have suffered in varying degrees from similar accidents. Further spreads from the original infiltration are usually due to causes other than those responsible for the original lesion. The far advanced case frequently remains so throughout a long period of observation, showing little or no tendency to, or evidence of, progression. The minimum case only occasionally will show progression into the far advanced group by a series of spreads. Effective treatment must depend upon the diagnosis being made as early during the prodromal period as possible and immediate bed rest provided. The closer to the onset of initial symptoms, and the postponement of the time of breakdown that treatment can be instituted, the greater will the results be from such treatment.

Regardless of how we approach the management of tuberculosis, we will persistently return to the two pillars upon which the entire problem rests, treatment and epidemiology. The one can be carried out to most advantage in the sanatorium; the other is more comprehensive and includes the sanatorium as well as the entire environment of the patient and his associates.

The recent work showing the prevalence of pulmonary tuberculosis among children of high school age, the advantage to the patient in establishing an early diagnosis, the significance of the skin reactions, all give abundant evidence of the fact that the effective control of tuberculosis is closely related to its epidemiology. Every sanatorium should be as active in the study of the epidemiology of the disease as they are in its therapy. Only by making the sanatorium a center in the community for the collection of data, the dissemination of knowledge and making epidemiological studies in the families who have members on the cure as well as making it a place to receive and care for those actually ill, can the institution serve its mission. The sanatorium must become more than a repository for sick bodies. It must be alive to its opportunities for study and service. If the sanatorium is to maintain its position of leadership in tuberculosis work it must offer both positive therapy to the sick and positive service to the community.

(To be concluded in next issue.)

HYPERLEUKOCYTOSIS IN DIABETIC COMA*

Karl W. Anderson, M.D.
Minneapolis

A MARKED leukocytosis is a frequently observed phenomenon in diabetic coma. Competent observers have agreed that this is not an infectious leukocytosis and is a characteristic of an uncomplicated diabetic coma. There is an apparent correlation between the amounts of acidosis (that is, the acetone, diacetic and B-oxybutyric acid) and the increase of the circulating leukocytes. Joslin[3] reports five cases of marked leukocytosis, the count ranging from 14,000 to 44,100 and without history of infection or hemorrhage from the stomach. Allan[1] likewise has reported five cases in which the leukocytosis ranged from 16,000 to 66,400 uncomplicated by infection. He brings out in his publication the difficulties sometimes observed in the differential diagnosis between diabetic coma and an acute abdominal condition. Klaus Barner[2] reports two cases in which the patients were in coma or precoma, and the blood examinations showed a distinct stimulation of the leukocytes. He found a marked shift to the left (Schilling's method). There was a great relative increase of neutrophils and shifting to myelocytes. He believes that the acetone bodies are probably the cause of the change in the blood.

In one of our cases to be reported, detailed hematologic study showed the response to be in the granulocytic series. Sabin[4] believes that the granulocytes are developed between the sinuses of the bone marrow and migrate into the sinuses when they are dilated. In her concept the oxygen tension in the bone marrow plays a very important part in the dilatation of the sinusoids. It may be that the noxious agent causing the increased circulation of white cells is the acetone bodies in the blood. These bodies may cause a dilatation of the sinuses in the bone marrow, hence, according to the Sabin theory, the increase in the circulating white cells. It is interesting to note that the lymphoctyes and monocytes were not particularly affected. What the relationship is between the age of the patient and the increased circulating white cells is questionable. We know that in youth there is a greater response in the white blood count to stimulation both by bacterial toxin and metabolic products. In the older case to be reported there was no detailed blood study made, but the white cell count reached 24,000 without any evidence of infection.

*From the Department of Medicine, University Hospital.

CASE REPORTS

Case 1.—Miss C., aged 15, Jewish.

Past History: She has been a diabetic for seven years, and during this time has been in coma three times. A diagnosis of diabetes mellitus was made for the first time during an attack of otitis media complicated by diabetic coma. We have no detailed report concerning the blood in the first attack of coma. She has been studied and followed continuously in the University Dispensary and Hospital from December 28, 1923, to date. During this time her diet was gradually increased until she was receiving carbohydrates 65, protein 55, and fat 150, with insulin 20, 10, 30, 10.

The day before admission the patient was slightly nauseated and did not eat much food and for that reason discontinued her insulin. The next morning a doctor was called who gave her 10 units of insulin. By noon she was nauseated to the extent that she was vomiting and complained of pain in the midepigastrium. She was then referred to the University Hospital.

Physical Examination: On January 23, 1928, the patient was admitted to the University Hospital, presenting the picture of diabetic coma with unusually pronounced and persistent Kussmaul breathing. The patient did not take her evening insulin and that night became nauseated and started to vomit and gradually went into deep coma. The body temperature on admission was 97, pulse 140. The systolic blood pressure varied from 80 to 60 and the diastolic from 30 to 0. Blood pressure gradually increased to systolic 115, diastolic 75. The eyes were soft, skin dry, chest negative. The heart was rapid and irregular, but on treatment became regular. On admission there were a few crepitant râles heard over the bases of both lungs, posteriorly, which did not persist. The abdomen was markedly distended with slight tenderness in the epigastrium. Reflexes were hyperactive. Temperature the first day reached 97 degrees Fahrenheit. The following days the temperature was not observed higher than 100.

Laboratory Examination: The blood showed 600 milligrams of blood sugar per 100 c.c. of blood and the reduction of the CO_2 combining power to 11 volume per cent (Van Slyke). The patient was brought out of coma by the routine procedure, outlined by Joslin. The urine contined a large mount of acetone and diacetic acid, a few red blood cells, and many

granular casts. This gradually cleared up. The Wassermann examination was negative. The blood urea nitrogen 16.

The interest centers around the behavior of the leukocytes. On admission January 23, 1928, white blood cells were 79,000; two hours later 72,000. The next morning, 13,000 and 14,000. Red blood cells were 5,070,000, hemoglobin 97 per cent.

	Blood Sugar	*Van Slyke*	*White Blood Count*
January 23, 10:30 A.M.	.600	11%	79,000
January 23, 4:30 P.M.	.520	15%	72,000
January 24, 8:00 A.M.	.066	32%	24,000
January 24, 2:00 P.M.	.090	40%	
January 25, 8:00 A.M.	.155	43%	14,000

Her diet was gradually increased until she was receiving 60 grams of carbohydrates, 55 protein, 140 fat, and with this she was receiving 70 units of insulin. After twenty-nine days in the hospital she lapsed back to coma due to inactive insulin. The blood sugar on February 27th showed 465 milligrams per 100 c.c. of blood and the reduction of CO_2 combining power to 9 volume per cent (Van Slyke). The patient was again brought out of coma by the same procedure.

Both times with the gradual improvement of the diabetic condition the urine, which was heavily loaded with acetone bodies, gradually cleared up and the white count approached normal.

	Blood Sugar	*Van Slyke*	*White Blood Count*
February 27, 1928	.465	9%	97,000
February 28, 1928	.319	31%	
March 1, 1928	.222	45%	22,000
March 2, 1928	.163	60%	14,000

The following detailed morphological study of the blood at the peak of the leukocyte count (97,000) was made by Dr. C. H. Watkins: The erythrocytes show a moderate anisocytosis, moderate polychromatophilia and an occasional normoblast. The neutrophiles are markedly shifted to the left as far as the leukoblast stage. The predominating cell is the myelocyte although numerous premyelocytes are present. The eosinophiles are likewise immature, most of the cells being in the metamyelocyte stage. The basophiles are increased in number but are, for the most part, mature. The lymphocytes are relatively decreased in number, but show no evidence of immaturity. The monocytes are slightly immature and the cytoplasm contains abundant azurophilic granulation. The blood platelets appear to be increased and are smaller than normal.

After the leukocyte count returned to normal, the morphological blood picture became entirely normal and remained so.

This response in the leukocytes is not present in the young diabetic only, for we have one other case in a patient forty-six years of age who had proportionately the same response. The following illustrates how difficult it often is to make a diagnosis of an acute abdominal infection in diabetic coma. Her cardinal symptoms were nausea, vomiting and pain in the epigastrium with a leukocytic response of 24,000. She was admitted to the University Hospital on two occasions in diabetic coma. The second time she had a definite history of upper respiratory infection, but the first time we were unable to demonstrate the infection. It is for this reason that this case is incorporated in this paper.

Case 2.—Mrs. M., aged 46.

History: She had had no serious illness during her childhood, but at eighteen years of age had an attack of smallpox. At forty-three years of age she had an appendectomy and it was during the routine examination preparing her for this operation that sugar was found in the urine.

The patient was put on a qualitative diet, taking insulin irregularly, usually 15 units daily. On July 3 she went on a weekend party. She became nauseated, had pain in the midepigastrium and then vomited. She then took 15 units of insulin and felt much better. That night her symptoms recurred and in taking her insulin she broke the needle and hence discontinued the use of insulin. She was taken to her home in rather critical condition and her home doctor made a diagnosis of intestinal obstruction. A consultant was called who recognized the condition as diabetic coma and who then referred her to the University Hospital on July 6.

Physical Examination: The patient was a tall, undernourished, white female in severe coma with marked Kussmaul breathing, and marked dehydration. The eyes were soft, tonsils small, neck normal. The lungs were negative, pulse 140, heart regular and within normal limits in size. Blood pressure 88/65. The abdomen was extremely tender in the epigastrium on palpation, but there was no rebound tenderness. Rectal and vaginal examinations were negative. The reflexes were hyperative. The eye-ground findings were negative.

Laboratory Findings: The blood on admission showed 450 mgm. of blood sugar per 100 c.c. of blood and the reduction of the carbon dioxide combining power was 7. Hgb. 100 per cent: r.b.c. 4,960: w.b.c. 24,000; differential p.m.s.s. 80 per cent, lymphocytes 20 per cent; Wassermann negative. Stool examination proved negative. *X*-ray of the extremities showed no calcification of the arteries.

The patient was brought out of coma by the same procedure as above.

	Blood Sugar	*Van Slyke*	*White Blood Count*
July 6th, 10:00 P.M.	.545	7%	24,000
July 6th, 6:00 P. M.	.468	11%	
July 7th, 8:15 A.M.	.078	44%	12,000
July 8th		65%	

She was discharged on a diet of 80 carbohydrates, 50 protein and 180 fat with 40 units of insulin.

A detailed study of the blood was not made in this case.

SUMMARY

1. Two cases of diabetes with coma are reviewed in which there was a definite stimulation of the white blood cells without evidence of infection.
2. This may be explained on the basis of the reaction to organic acids such as beta-oxybutyric acid in high concentration in the blood.
3. The age of the individual might explain the response in the younger individual.
4. Besides the increase of the mature cells of the neutrophilic series there was an increase of the immature cells in the same series to such an extent that the morphological blood picture superficially simulates that of myelogenous leukemia.

CONCLUSION

1. Hyperleukocytosis occurs in diabetic coma.
2. This leukocytosis occurs without a concomitant infection.
3. The leucocytosis may be due to acid bodies.
4. In children the leukocyte count in coma may be higher than in adults.

THE NAME IS VIOSTEROL

Several preparations of irradiated ergosterol, given for its Vitamin D effect, and christened "Viosterol" by the Council on Pharmacy and Chemistry, are now available on the market. Abroad the product is known by other names, and some distributors are attempting to force the foreign products on the American consumers. Long before anything definite was known as to its actual possibilities for good or harm in the human body, commercial firms attempted, as usual, to get it before the medical profession. When reports of the possible dangers began to appear in foreign medical literature, physicians who were using the product and representatives of the Wisconsin Foundation persuaded the promoters to withdraw the product until dosage and dangers could be established. Then when the time came to release the product again most leading manufacturers agreed to the use of the common name selected by the Council on Pharmacy and Chemistry as the name for the preparations that met its standards. Mead Johnson & Co. of Evansville, Ind., thinking perhaps that its original promotion of its product, Acterol, entitled it to special consideration, has refused to abide by the name chosen by the Council. After careful consideration of all the facts, the Council on Pharmacy and Chemistry decided that the firm had no such claim. Physicians must recognize the necessity for upholding to the fullest extent the Council's decision regarding irradiated ergosterol. If this product is prescribed, the name to be used is "Viosterol" and the brand specified one of those accepted by the Council. Not "Vigantol," not "Acterol," but "Viosterol." (Jour. A. M. A., October 5, 1929, p. 1066.)

MORE MISBRANDED NOSTRUMS

The following products have been the subject of prosecution by the Food, Drug and Insecticide Administration of the United States Department of Agriculture which enforces the Federal Food and Drugs Act: Acid Iron Mineral Compound (A-I-M) (Acid Iron Mineral Percolating Corporation) consisting essentially of a brownish-colored, slightly acid solution of iron, aluminum and magnesium sulphates, with a small amount of phosphates. Allenrhu (Alle-Rhume Remedy Company) consisting essentially of sodium phosphate and sodium sulphate, with small amounts of sodium salicylate and colchicine, some free acid, in a mixture of glycerin and water, flavored with licorice and wintergreen. Nozol (Nozol Company, Inc.) consisting of a heavy petroleum oil, containing menthol and camphor, colored with a red dye. Lane's Cold Tablets (Kemp and Lane, Inc.) consisting essentially of acetanilid, with small amounts of quinine sulphate, camphor and aloin. Asceine (Serra, Garabis and Company) consisting essentially of caffeine, phenacetin (acetphenetidin) and aspirin (acetylsalicylic acid). Zonite (The Zonite Products Company) consisting essentially of a solution of sodium hypochlorite, yielding approximately 1 per cent of available chlorine. Fildrysine (Drug Company) consisting essentially of iodides of potassium and sodium with small amounts of compounds of arsenic and mercury, a trace of berberine, glycerin, alcohol and water. Jayzon's Laxative Cold Tablets (D. C. Leo and Company, Inc.) consisting essentially of acetanilide, with a small amount of cinchona alkaloids and certain extracts of plant drugs, such as aloe, podophyllum and capsicum. (Jour. A. M. A., November 2, 1929, p. 1404.)

THE USE OF SODIUM CHLORIDE IN THE TREATMENT OF VARICOSE VEINS

M. G. Gillespie, M.D., and W. G. Strobel, M.D.
Duluth Clinic
Duluth, Minnesota

THE treatment of varicose veins by the injection method has now practically superseded the older methods of surgical excision. In fact, this method of treatment has been so popularized, especially by Health columns in the daily press, that many sufferers with varicose veins and varicose ulcers are demanding this form of treatment. The injection treatment of veins is becoming so popular that it is absolutely imperative that the medical profession thoroughly acquaint itself with the condition, indications and contra-indications for the treatment, and the technic.

In this treatise we wish to summarize the end-results obtained and the technic used in approximately four hundred injections in eighty cases of varicose veins and varicose ulcers treated since January 1 of this year, and using only one sclerosing agent, namely, 20 per cent sodium chloride solution.

Previous to this time other sclerosing solutions, namely, mercuric chloride, quinine and urea, sodium salicylate, and calorose, were used, but rather aimlessly and without much attempt to follow the results obtained. However, since the first of the year we have kept an accurate account of each case treated, and have systematized our technic, so that it is now much more satisfactory, and we believe the results much more promising.

The injection treatment of varicose veins is by no means a new procedure. It was first introduced in 1851 by Pravatz. In 1894, Delores proved that the results of the treatment were due to the effects of the solution on the intima of the vein rather than to the solution itself. Linzer, Noble and Sicard, on the Continent, have done the most to establish this procedure. In this country, Hayes, and more recently McPheeters, have done much to popularize this method of treatment. Within the past year numerous contributions have been offered.

There are certain types of varices which yield readily to treatment. The isolated varix or the tortuous cavernous mass of varices is ideal for injecting purposes. The small cutaneous dilatations we do not attempt to treat at all. As a rule, they do not cause any symptoms, and the worst that can be said about them is that they are unsightly. We are rather skeptical of those cases where there is a uniform dilatation of the larger trunks of the saphenous vessels. Quite often, especially in men doing heavy work, one finds that all the large superficial veins, not only of the lower limbs but also of the upper extremities, are very prominent. Unless one of these on the lower limb is enlarged out of all proportions it would be better not to attempt obliteration. In two or three cases in which there was a unilateral dilatation of the long saphenous vein, even up to its union with the femoral, a thrombosis has been obtained, but more recently in these cases we have been practising ligation of the saphenous vein at the foramen, with extirpation of the vein to the knee, followed by injections of the tortuous varicosities of the leg. We believe that this is a safer practice, although we do not hesitate to inject either isolated varices or tortuosities on either thigh.

The technic is one which we have established through experience, and one with which we feel we get the best results. In the average case of varicose veins, where the patient is ambulant, one can feel quite certain that the deep venous circulation is competent. We find that it is very seldom that we have to make any special tests to determine the competency of the deep circulation. After a little experience one will get to suspect these cases in taking the history and also on the examination of the limbs. However, if there is any question of the deep circulation it is a simple and safe measure to bind the leg snugly and have the patient walk. If the patient

complains of pain in the leg, injections should not be attempted.

Before the treatment is begun an understanding is had with the patient. It is explained that this will be a course of injections at intervals of three to ten days, and that the treatment will probably extend over a period of from six to twelve weeks.

When the treatment is begun the patient is seated on the end of the table, with the feet resting on a stool. The sites of injection are approximately located. After the tourniquet is applied the patient is asked to lie flat, with the leg elevated even with the body. The site of injection is selected, and this usually the lowermost point of the varices, and the area is sterilized. Then a 20-gauge needle is inserted into the varix, although the size of the needle depends a good deal upon the size of the varix, and blood is then aspirated into the syringe, which usually contains 10 c.c. of the 20 per cent sodium chloride solution. When one ascertains definitely that the needle is in the lumen of the vein, the assistant raises the leg so that it is slightly higher than the body, and after the tourniquet has been released and the veins have collapsed, from 5 to 30 c.c. of the solution are slowly injected, repeatedly making sure that none of the fluid is escaping into the perivascular tissues. Immediately after withdrawing the needle, compression is applied at the site of injection. The leg is maintained in the elevated position. After the cramp subsides (which usually follows each injection, but lasts only a minute or so) a second, or even a third injection may be performed. As a rule, the injections are confined to the varicosities of one leg, and this is continued until the greater part of the vessels are thrombosed before beginning treatment on the other leg. This insures one good leg, as there is usually some discomfort following the development of the thromboses. If 20 to 30 c.c. of the solution are injected at one point this is usually considered sufficient for the day. However, if only 5 or 10 c.c. of solution are injected at one time, three or four of such injections may be completed at one sitting. After the injections are made, a sterile piece of gauze is placed over the points of puncture, and an elastic bandage is applied quite firmly around the extremity, beginning at the foot and continuing to or above the knee, with the leg still in the elevated position. After the bandage is applied the leg is lowered, but the patient is asked to remain quiet for ten or fifteen minutes. The patient is then allowed to be up, and to return home, but is asked to return again in three or four days. Usually at this time, there is quite an extensive thrombosis, which is rather tender, and no more injections are attempted until some of the soreness and pain have subsided.

These treatments are continued then at intervals, gradually working higher and higher on the extremity, until all the varicosities are thrombosed.

In the treatment of varicose ulcers the sclerosing of veins beneath and about the ulcer has usurped all other forms of treatment. This method, combined with immobilization, results in immediate comfort and rapid healing. Frequently there seems to be very little evidence of varicose veins in connection with the ulcer, but careful palpation will almost always disclose veins, either in the bed or at the circumference of the ulcer.

Recurrences of ulcerations are quite certainly due to the fact that some of the varicosities have been missed, and a further search will usually elicit a varix.

The same technic is carried out as described above for the treatment of complicated varices.

After the injection is completed the ulcer is strapped with adhesive, beginning well below and extending well above the ulceration. This is changed every three or four days, and the injections are repeated at intervals, until all the demonstrable varicosities are thrombosed. Almost always, within forty-eight hours after the first treatment, the patient is entirely comfortable and epithelialization can be demonstrated at the margins of the ulcer. Very large ulcers, some half circumscribing the leg, have been healed in this manner.

After healing is complete, the patient is advised to continue to wear a spiral elastic bandage for an indefinite period, merely as a protection and support.

The contra-indications to the injection treatment of veins might be divided into local and constitutional conditions.

The constitutional conditions which might contradict injections are diabetes, marked peripheral arteriosclerosis and pregnancy. In one case, in

the early months of pregnancy, we treated in this manner and got a splendid result, but I believe in general it would be using better judgment to wait until the termination of the pregnancy.

The chief local conditions which might contradict injection are a local infection in an ulceration and a phlebitis. Where infection is present in an ulcer the condition is treated by hot packs until the infection subsides. Where a local phlebitis exists the condition is treated by rest, immobilization, and cold packs. As soon as the phlebitis subsides the remaining varicosities may be injected.

Summarizing the results of four hundred and five injections in eighty-one cases, I have divided the cases into several groups.

In three cases the varicosities had been previously operated and a recurrence developed. Thirteen cases had a complicating varicose ulcer. In twenty-three cases the condition was very extensive, involving both the small and the large saphenous veins. In thirty-six cases there were single groups of nodular varices, and in nine cases a single varix. In every case a good result was obtained, and the patient was well satisfied with the result. In a few cases, especially of the milder types, results were excellent.

This method of treatment, using sodium chloride as the sclerosing agent, is not without its complications. In nine there was quite a marked induration at the site of injection. This complication is undoubtedly due to leakage of the solution through the puncture in the vein wall or due to the fact that the varix is very large and superficial. We have been able to avoid this complication by entering the needle in the skin at a distance from the varix, and traversing quite a thickness of subcutaneous tissue before entering the vein, much in the manner of aspirating a cold abscess.

Six cases developed a marked chemical phlebitis. This was so extensive as to cause a good deal of discomfort. Much of this can be alleviated by rest and the application of cold compresses.

In eleven cases there was some sloughing at the site of injection. In the majority of these cases it was merely a dry slough, which gradually separated and healed over. With experience we have been able to avoid this complication by being absolutely sure of having the needle within the vein. If there is any question the needle is withdrawn without injecting any of the solution. I find that by placing the forefinger of my left hand gently over the point of my needle I can absolutely determine whether the solution is entering the vein or not. When this complication does arise it is evident in a minute, as demonstrable by the blanched appearance of the skin and the bluish-purple irregular border. We feel that it is not a good practice to immediately excise this area. There will be a stinging, burning pain at the site for a period of twenty-four hours, and this will be followed by the development of a dry gangrene, which gradually separates, and the defect slowly fills in with granulation tissue. The immediate injection of the area with hypotonic saline solution is suggested if such an accident should occur.

CONCLUSION

The experiences, the results obtained, and the technic used in four hundred and five injections in eighty-one cases of varicose veins and varicose ulcers, using a 20 per cent sodium chloride solution as the sclerosing agent, are reported.

This sclerosing solution produces a more adherent and extensive thrombosis, giving a more satisfactory end-result. The objections to its use are, first, that it produces a sloughing if allowed to escape outside of the vein wall, and, secondly, that in the majority of the cases it produces a severe cramping pain, which lasts from one to two minutes following injection.

RHEUMATIC FEVER: A COMMUNICABLE DISEASE*

J. C. Hathaway, M.D.
Minneapolis

DURING the past year there have been eleven cases of acute rheumatic fever among students on the University of Minnesota campus. Five of these were among Farm School students on the Agricultural campus and six among University students on the main campus. All cases occurred within a relatively short period of time, constituting a mild epidemic of this disease. A brief review of the literature shows that epidemics of this kind are not uncommon and each outbreak presents points of clinical and epidemiological interest. This paper is presented particularly from the epidemiological viewpoint.

In order to increase the size of the series and to get more data, a review of cases in students since 1922 is also presented. In all there are thirty-two cases presented here. These were studied in two separate groups for there were more data available from the recent epidemic; but, in summarizing the results, all will be considered together.

CLINICAL AND EPIDEMIOLOGICAL DATA

The age incidence varied from thirteen to thirty-one years, the average being twenty years. There were twenty-nine males and three females. The time in the infirmary varied from 1 to 97 days, the average being about 22 days. These figures, however, do not represent the total duration of disability, as a number of the patients were sent to their homes or transferred to other hospitals. This applies particularly to those who spent only a few days in the infirmary. Four gave a previous history of rheumatic fever.

Fifteen cases occurred among Farm School students on the Agricultural campus and four among Agricultural College students on the same campus. Thirteen cases occurred among all other colleges on the main University campus. These data seem significant, as the Agriculture group forms less than ten per cent of the total University enrollment. This was probably due to several factors. The health habits of this group as a whole are not as good as in the larger University group. More foci of infection are present. Also, this group, coming largely from rural districts, have had fewer previous contacts and less chance for immunity, and on coming to school have a greater degree of segregation and closer contacts due to the fact that most of them live in dormitories, whereas the larger University group live almost entirely in private homes.

The actual clinical course and treatment will not be considered here. Clinically, all of these cases were typical acute rheumatic fever, with or without complications. Treatment was under the supervision of a competent internist, and according to usual prescribed methods. There was one death in the series.

A search for foci of infection was made in each case. In ten cases no focus could be found. In the cases in which foci were found, the tonsils were the probable foci in nineteen cases, teeth in four cases, sinuses in four cases, and osteomyelitis possibly in one case.

Thirteen cases were uncomplicated rheumatic fever. Of the nineteen cases with complications, endocarditis was the complicating factor in fifteen, endocarditis and pericarditis in two, pericarditis alone in one, bronchopneumonia in three, pleurisy in one, acute glomerulo-nephritis in one and old mitral regurgitation in one case.

Thirteen cases were admitted to the infirmary for some other illness a short time before developing rheumatic fever. Some of these may have been a forerunner of or may have initiated the attack. Of these thirteen, seven were in with tonsilitis, four with respiratory infections, one with maxillary sinusitis, and one for submucous resection.

Twenty-seven of the thirty-two cases occurred during the month of January, February, March and April. There were two cases in May, one in June and two in November. These data correspond with those of some of the other series reported in the literature, most epidemics occurring in the early months of the year.

In the five cases occurring among Farm

*From the Department of Preventive Medicine and Public Health and the Students' Health Service, University of Minnesota.

School students this year, it was possible to establish contact with known cases of rheumatic fever in each instance. No great significance can be attached to this, however, as there are too few cases from which to draw definite conclusions.

DISCUSSION

A partial review of the literature on the epidemiology of rheumatic fever has been made to bring out more strongly the facts presented in this series. The following points are those of most interest in this relation.

1. *Communicability.*—As early as 1864, Hirsch in his Geographical and Historical Pathology states that "rheumatic fever deserves an assured place among acute infectious diseases." Newsholme in 1895 made an exhaustive study of the known facts and expressed the belief that "rheumatic fever was a specific febrile disease always endemic and at intervals epidemic or even pandemic." Numerous others since that time have studied this problem. Fairly recent articles have been published by Hiller and Graef, Atwater, Mackie, Abeloff and Sabel, Boas and Swartz and others. The general conclusion reached is that rheumatic fever has many of the characteristics of other infectious diseases with a low grade of contagiousness but that at times and under special circumstances it may assume epidemic proportions. Fiessinger, Friedlander, Miller, Swift and others give studies pointing to the possibility that house infections, especially where crowding and unhygienic conditions are important factors, occur in rheumatic fever. Cheadle, Branson, MacCullun, Mantle, Ingerman and Wilson present studies showing the high family incidence. Abeloff and Sabel, Faulkner and White also show that rheumatic fever, like tuberculosis, is to a considerable extent a familial disease, their conclusions from the evidence presented being that families of "rheumatic" patients are more than twice as apt to have another member with a rheumatic infection as families of "non-rheumatic" persons. St. Lawrence observes a higher family incidence for rheumatic fever than for tuberculosis.

In the series presented here the higher incidence in the more closely segregated group of Agricultural students points strongly to the assumption that communicability must have been an important factor. Actual contact with known cases could be demonstrated in almost half of the 1929 cases.

2. *Focal Infection.*—Focal infection in rheumatic fever is still a debatable question. Many prefer that the phrase "portal of entry" be used in its place as it expresses better the real situation. The literature is replete with writings on this subject so only a few will be quoted. Marshall, Houston, Miller, Mackie and many others stress the tonsils as foci of infection. Shaw, Hartzell and others show the importance of oral infections other than the tonsils. Several authors have called attention to other more uncommon foci. Kaiser studied 48,000 children, 28,000 in whom tonsils were removed and 20,000 in whom they were not removed, and concluded that the tonsillectomized child is insured somewhat greater protection against this infection. Ingerman and Wilson believe that tonsillectomy does not by any means always protect against infection, but that other portals of entry must be considered.

In this series tonsillitis in a number of cases and sinusitis in a few cases initiated the attack and were considered as probable portals of entry. In a number of other cases tonsils or teeth were considered to act as foci of infection.

3. *Seasonal Variations.*—A number of the writers previously quoted have called attention to the seasonal occurrence of rheumatic disease. In some localities it is of more frequent occurrence in the spring, while in others it is more common in the fall. In general, the months of March, April and May seem to be the most common.

The early months of the year, January, February, March and April, are evidently the most common in this locality, judging from the material presented.

4. *Age.*—Age incidence is given in almost all of the articles reviewed. Rheumatic fever may occur at almost any age, and is quite common in children, but the highest incidence is given for the ages from ten to twenty.

This age group takes in all of the cases presented in this series.

5. *Geographical Distribution.* — Harrison, Shaw, Clark and others show that this disease is comparatively common in the colder climates and comparatively uncommon in warmer climates, being rare in the tropics.

The climate in this locality seems to be a fairly favorable one for this disease.

6. *Relation to Rainfall.*—A number of writers both in this country and in the British Isles have shown that there is an increased incidence and a higher death rate during the years or months when there is a large rainfall. Several authors have called attention to the fact that rheumatic fever is most common in the British Isles when dampness is common. These facts are interesting but bear no apparent relation to the present series.

7. *Etiology.*—The bacterium which causes rheumatic fever is still a debatable question, both a streptococcus and a diplococcus having been described. Blood cultures were made on three students in the 1929 group by Dr. W. P. Larson of the Bacteriology department of the Medical School. The first two cultures were negative, possibly because they were not taken early enough in the course of the disease. In the third a gram-positive diplococcus was found, which would grow only on yeast extract broth.

SUMMARY AND CONCLUSIONS

1. Thirty-two cases of acute rheumatic fever among students at the University of Minnesota are presented.

2. Nineteen cases or 60 per cent occurred among the relatively small segregated group of students on the Agricultural campus, which comprise less than 10 per cent of the University enrollment.

3. Foci of infection were found in twenty-two cases or 69 per cent.

4. Complications occurred in eighteen or 56 per cent.

5. Twenty-seven cases or 85 per cent occurred during the months of January, February, March, and April.

6. Rheumatic fever is a communicable disease, and seasonal epidemics are not uncommon.

THE D. A. WILLIAMS QUACKERY

The Dr. D. A. Williams Company of East Hampton, Conn., has been operating a piece of mail-order quackery for many years. More than ten years ago the Bureau of Investigation of the American Medical Association reviewed the history of the concern and brought out that the business had become so extensive that it had given the little village of East Hampton, with a population of less than 1,500 people, a postoffice of the second class! At the time, form-letters sent out by the D. A. Williams concern were signed, variously, "Theodore Flaacks, President," "J. M. Stearns, Manager," and, occasionally, "Dr. E. E. Williams, Medical Advisor." It was also shown that the Dr. D. A. Williams concern had made a practice of selling to letter-brokers the original letters that had been sent to it by prospective victims. It was shown, too, that the preparation sent out by the company for the alleged cure of all "uric acid troubles" was essentially a solution of potassium acetate, colored and flavored with wintergreen. Examination of a specimen sent out by the D. A. Williams concern in October, 1929, indicates that the composition of the nostrum has not changed. Recently the National Better Business Bureau investigated the concern. With the assistance of the Medical Information Bureau of the New York Academy of Medicine, four report blanks were filled out and sent to the Williams Company from different parts of the country to determine whether the company declined to sell its product to those who were suffering from serious ailments. Due to the fact that diagnosis by mail is declared to be unscientific and untrustworthy by medical authorities, pronounced symptoms were indicated. In reply a diagnosis and prescription were returned under the signature of Dr. Wilson Powell, New Haven, Conn. (Jour. A. M. A., November 9, 1929, p. 1493.)

BOROCAINE NOT ACCEPTABLE FOR N. N. R.

The Council on Pharmacy and Chemistry reports that under the proprietary, non-descriptive name "Borocaine," Sharp & Dohme, Baltimore, market procaine borate, the boric acid salt of the base procaine. The product was placed on the market on the basis of work published by Copeland and Notton, who adopted the name Borocaine to designate the borates of various anesthetic bases with which they experimented and who, according to Sharp & Dohme, gave their approval to the British Drug Houses to manufacture procaine borate under the tile Borocaine. The A. M. A. Chemical Laboratory examined the product marketed as Borocaine and reported that it was the borate of the base procaine —that is, procaine borate. From a study of the literature it was concluded that the procaine borate studied by Copeland and Notton agreed essentially in composition with the procaine borate prepared and described in 1910 by Einhorn and Uhlfelder. Since procaine borate was previously described in the literature, the Council could not recognize the name Borocaine on the score of novelty, and since neither Sharp & Dohme, the British Drug Houses nor Copeland and Notton discovered the therapeutic value of procaine or even the properties of procaine when contained in a solution in which ionization of the procaine salt does not accur, the Council could not recognize the name Borocaine under the clause which permits the recognition of a proprietary name for a previously known substance discovered to have therapeutic value. The Council therefore declared "Borocaine" unacceptable for New and Non-official Remedies because the application of a proprietary name to procaine borate is considered not to be in the interest of rational therapy. (Jour. A. M. A., October 26, 1929, p. 1309.)

CAREFUL OBSTETRICS

J. H. Simons, M.D.
Assistant Professor of Obstetrics and Gynecology, University of Minnesota
Minneapolis

I SELECTED this title, "Careful Obstetrics" because there has been in recent years a renewed interest in maternal and infant welfare and that interest must be maintained by us through reiteration of the principles involved.

The necessity of better obstetric care is shown by the facts that approximately seven in every 1,000 pregnant women die (20,000 die yearly in the United States alone), some 100,000 babies die yearly under the age of one month and every year there occur 100,000 stillbirths. In addition puerperal morbidity due to parturitional injuries, puerperal infection and post-partem hemorrhage often leaves its dire impress in the form of chronic invalidism of the mother. Trauma to the infant, if not sufficient to cause death, often produces permanent defects.

It is generally agreed that the present high mortality and morbidity can be greatly reduced by proper prenatal, natal, and postnatal care. Our greatest advance is shown in lessened morbidity, but fetal and maternal mortality has changed too little during the last twenty-five years.

What factors are responsible for this condition? There is a lack of education of the laity as to what constitutes proper obstetric care. The state as well as the physician should be responsible for the dissemination of this knowledge. Midwifery is still a factor but a constantly decreasing one. There is a great need for better undergraduate and postgraduate instruction and a renewed sense of responsibility by the physician who accepts an obstetric case, thus raising the practice of obstetrics to the dignity of an art, not a sideline in the practice of medicine. Too often there is the feeling that the majority of cases will terminate happily without any attention whatsoever except to be present at labor to tie the cord and Credé the placenta or possibly to end the case abruptly by the inpudicious use of pituitrin or forceps. With present-day ease of communication and transportation, the problem of the rural physician is not different from that of the urban physician. One can practice better obstetrics if there is the will to do it. The only problem is proper remuneration and this is a matter for your medical society to discuss and agree upon.

The best single argument for pre-natal care is the expression of Moreceau, "that pregnancy is a disease of nine months duration." We know that very few women pass through the pregnant state without some disturbance more or less momentous, either physical or psychical. Assuming that the physiologic processes of a normal woman should make proper adjustments to the pregnant state, the majority of women suffer during this attempt with such disturbances as malaise, nervous instability, nausea and vomiting, or exhibit evidence of great physiologic load, by acidosis, glycosuria and albuminuria.

Again her reaction to the pregnant state often results in such marked imbalance as to produce a serious condition such as pernicious vomiting, nephritic or pre-eclamptic toxemia, or true eclampsia.

Prenatal care will disclose these conditions at their inception and with proper treatment will effect a cure in most instances.

The first principle of prenatal care is a careful history. Tuberculosis, insanity, cancer, hemophilia, in the family history is important. Barnes said, "Pregnancy is a test of bodily soundness." Previous diseases may markedly influence the pregnancy, parturition or puerperium. Who has not seen the rickety pelvis, with consequent dystocia; the heart damaged by some infectious disease such as diphtheria, influenza, or articular rheumatism undergo decompensation under the stress of labor; the deleterious effect of pregnancy on tuberculosis which flares up in the puerperium; a chronic nephritis which progresses to a pronounced insufficiency through a toxemia, usually at the end of the second trimester? These cases require the most meticulous care and fine judgment in their treatment.

A history of previous gynecologic operations

*Read at the sixty-first annual meeting of the Wabasha County Medical Society, Wabasha, Minnesota, July 11, 1929.

may be important as to probable complications. The woman who has had an anterior fixation of the uterus is faced with the possibility of miscarriage or dystocia; the one with an amputated cervix with prematurity or dystocia. The one with the over-corrected rectocele may require an episiotomy to prevent laceration into the rectum or fetal death from intracranial hemorrhage, due to pounding of the head on the pelvic floor; the one who has had a previous cesarean section is likely to require at least the new low, extraperitoneal operation.

The venereal question should be put and the presence of infection determined by laboratory tests. Rarely does one find a smear positive for gonorrhea, but stigmata such as infected Skene or Bartholine glands or the so-called gonorrheal macule at the orifice of the latter, are sufficient evidence that the disease exists, and indicate the necessity for energetic treatment. The results from antisyphilitic preparations are next to marvelous in pregnancy.

The history of previous pregnancies as to duration, termination, type of labor, ante-natal and post-natal complications are important. Parturitional accidents such as premature separation of placenta, retained placenta, post-partum hemorrhage often recur and with this information in mind one can be on guard.

Minor symptoms such as nausea and vomiting which 50 per cent of pregnant women have more or less should be all noted. Many women consider this as a normal phenomenon, but if neglected it may develop into a pernicious form. Intravenous glucose with or without insulin prevents many therapeutic abortions which formerly had been necessary to preserve the health or life of the mother.

Symptoms such as headache, blurred vision, and epigastric pain should be investigated. Occurring in the last trimester these complaints have a special significance and may indicate an impending eclampsia. Infections of the nose and throat and particularly of the sinuses is a frequent cause of puerperal sepsis. Caries of the teeth indicate faulty calcium metabolism, which may be corrected by cod-liver oil and sunlight, or alpine lamp. It is now believed that the calcium metabolism at this time has a great influence upon the eruption and development of the child's teeth.

A thorough physical examination is due every pregnant woman. Foci of infection should be discovered and eliminated as far as possible. Thyroid enlargement may require treatment. Tuberculosis healed or active may require therapeutic abortion. Cardiac disease is an indication for constant vigilance and treatment and may require therapeutic abortion or, if seen late in pregnancy, cesarean section under local anesthesia. Bimanual examination in the early months may reveal a retroversion which if not corrected spontaneously or manually might become incarcerated and result in an abortion and sepsis. Tumors of the uterus of ovaries may be found. Varicosities of the extremities, aside from their unsightliness, produce aching legs and invite thrombophlebitis during the puerperal period. Elevated blood pressure, taking 130 as the upper limit of normal, points toward a developing toxemia even before albuminuria is present.

The average physician will not take pelvic measurements. There is no excuse for the neglect of such a simple but informative procedure.

The determination of the presentation and position of the fetus during the last trimester will at times allow a malposition to be corrected before labor.

Finally the mother should be supplied with information such as is given in the pamphlet, "Prenatal Care," furnished by the U. S. Department of Labor, which gives her information in simple terms regarding hygiene suitable for the pregnant state and in addition information concerning the care of the baby.

The patient should visit her physician every three weeks for the first six months, every two weeks thereafter, furnishing a specimen of urine every week during the last six weeks. At these visits, weight should be recorded, adverse symptoms noted, blood pressure readings taken, urine examination made and the condition of the fetus ascertained.

Only by proper prenatal care can many of the complications of childbirth be prevented. Our greatest opportunity lies in the prevention of fetal deaths, 34 per cent of which are due to syphilis and 72 per cent to syphilis, dystocia, toxemia and prematurity in the order named. Polak says, "Conscientious pre-natal care could obviate the death of one-half of the children who now die within the first month of puerperium." If so, 50,000 children are needlessly sacrificed each year.

Adequate care during labor is not often obtained. This is due to many causes: economic, the exigencies of medical practice, insufficient training, the personal equation involving conscientiousness, skill and niceties of judgment. Obstetrics is the poorest paid portion of medical practice, but it should be and is the most gratifying. Many obstetricians claim that obstetrics is a surgical specialty. While it is true that surgical efficiency is a necessary qualification of a good obstetrician, the bulk of obstetrics will always be done by the general practitioner. His dearth of surgical ability can be offset by conscientious effort with the skill that he possesses.

The one greatest need of the woman to be confined is her share of our time—the very thing we have the least of. There is no comparison between the results obtained by "hit and run" obstetrics and that obtained by adequate supervision.

The woman in labor and the fetus are beset with dangers more fulminating and immediate than the acute surgical case.

In the conduct of labor lies our greatest opportunity to change the existing figures of morbidity and mortality of the mother and child. Here the information gained by the prenatal care becomes valuable especially with regard to the blood, heart, lungs, kidneys and bony pelvis. Often we can predict the complications likely to arise in a particular case and be prepared to meet them. By observing the character of the contractions we can stop ineffectual ones by morphin, stimulate them by pituitrin or control them by anesthesia, of course giving due consideration to the stage of labor and anomalies of the child, passages and bony pelvis. The first essential is to know the position of the fetus. This is obtained by abdominal palpation and confirmed by rectal examination. The condition of the fetus should be noted at regular intervals particularly during the second stage. Rectal examination is a most satisfying diagnostic procedure and will eliminate vaginal examinations in 80 per cent of labors. With it can be determined the presence or absence of engagement, the condition of the cervix, the amount of forewaters and progress of labor.

Rigid asepsis should be maintained, as puerperal infection is the greatest cause of maternal morbidity and mortality. The parturient tract may be considered as an open wound and sepsis as a wound infection. Vaginal examinations, injudicious use of forceps, ill-advised intra-uterine manipulation, the fads of obstetrics, such as Potter's version and early forceps, help to maintain that 40 per cent of maternal deaths which are due to infection.

"More women die from accidents of the third stage than the other two combined." Post-partum hemorrhage is a fearful emergency. It may be insidious or acute and requires watchfulness, accurate estimation of blood loss, quick judgment and energetic treatment. The placenta should be given time to separate, should be Credéd gently, and examined thoroughly. Retention of a piece of placenta often produces sepsis and retention of membranes, sapremia and prolonged convalescence.

Strenuous methods in the resuscitation of the child should be avoided. Usually the child does not get his share of post-natal attention. The fact that as many children die in the first month as in the next eleven months deserve our consideration. Deaths are sometimes due to an enlarged thymus, which is remediable, or to congenital heart, which, while not curable, brings humiliation if not diagnosed.

The post-natal comfort of the mother is often neglected. Aseptic technic should be continued and applied to the breasts, treating fissures which if persistent may result in breast abscess. Persistent lochia rubra and frank hemorrhage should be controlled. Every effort should be made to locate the source of any fever and the perineal repair should be inspected.

Obstetrics, which should be an art, is a neglected branch of medicine both in its teaching and its practice. Education of the laity as to the value of pre-natal care, more undergraduate and postgraduate instruction, and conscientious usage of the knowledge that the practising physician now possesses will prevent a large percentage of the cases resulting in chronic invalidism and untimely death.

Hot Springs Clinic
Hot Springs, South Dakota

De Schweinitz describes ulcus rodens or chronic serpiginous ulcer of the cornea, as it is sometimes called, as a creeping ulcer which begins usually at the upper edge of the cornea as a superficial lesion separated from the healthy portion by a gray, opaque rim, which is usually undermined. The deeply undermined conjunctival edge of the ulcer is a striking feature. Vessels may pass to this ulcer and cicatrization apparently begin, but it relapses quickly and may spread until the whole cornea is traversed and sight is destroyed. The cornea is not usually perforated. The process may last from two to ten months or longer. The etiological factor has not been determined. The involvement seems to be limited, almost always, to the superficial layers of the cornea, according to Feingald. Prognosis is unfavorable. The treatment consists of relief of the pain and photophobia. The use of atropine and dionin, antiseptic Collyria in the cul-de-sac, hot compresses, or powdered calomel is indicated, and even paracentesis, curettage, conjunctival flaps, foreign protein injections, etc., may be resorted to if the earlier measures fail. Any evidence of focal infection in the teeth, tonsils, or sinuses should be attended to.

Fig. 1. Appearance of the eye on admission.

CASE REPORT

Mrs. E. F. came into the office on June 14, 1928, complaining of a soreness and redness of the right eye, which had become progressively worse for the past

Fig. 2. Schematic drawing of the condition of the eye on admission.

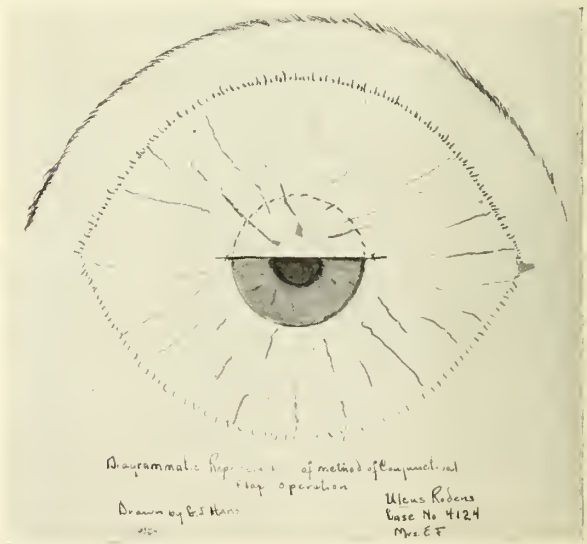

Fig. 3. Diagrammatic representation of the method used in the conjunctival flap operation.

four weeks. She had been treated by her local physician without any improvement. There was edema and ptosis of the right lid, marked lacrymation and photophobia. The right pupil was irregular and partly dilated. The tension was not increased. The vision was: right eye 20/200, left eye 20/20. There was an ulcer near the limbus in the eleven to one o'clock portion extending four millimeters towards the center of the cornea. The edges of this ulcer were undermined and the floor presented a dirty, scooped-out appearance. There were new blood vessels extending from the conjunctival edge and the ocular conjunctiva was injected over a triangular area with the ulcer as an apex. There was a mottling of Descemet's membrane and the iris was of a dirty, grayish appearance. The cornea was hazy, and the view of the fundus was indistinct.

General examination revealed no abnormalities. The patient was four months pregnant, the urine and blood were normal. The blood Wassermann was negative. *X*-ray of sinuses showed a very low grade chronic ethmoiditis. Teeth and tonsils were not diseased. Eye culture was positive for staphylococcus and pneumococcus. The patient was hospitalized and atropine instilled into the eye. Hot compresses were used and the ulcer was curretted. Calomel was applied to the ulcer locally. Boiled milk was injected into the gluteal muscles until a good reaction was obtained.

This treatment was continued six weeks and the eye did not show the expected improvement. For this reason it was decided to do a conjunctival flap operation. The method of Kuhnt was used as illustrated in the accompanying diagram. The flap was left in place five days and then removed. The ulcer healed rapidly from that time on, and three weeks later the patient was discharged with 20/30 vision in the right eye.

POPLITEAL ANEURYSM

REPORT OF CASE

A. E. Olson, M.D.
Duluth, Minnesota

The patient, G. E., seventy-four years of age, had been ill acutely four days before coming under our care.

Present Complaint.—

1. Pain, sudden and severe in left knee and leg.
2. Coldness and numbness of left extremity below the knee.
3. Swelling and discoloration of left leg.

Onset and Course.—The patient had noticed a pecular heavy lagging sensation in the left leg for the past year. He had not given this any particular attention because he did not have distress or pain and had worked as usual.

On June 12, 1929, he made a long trip by auto, driving almost continuously fourteen hours. On arriving at his destination, he stepped from the car and was suddenly seized with a very intense pain in the left leg from the knee down. He buckled and fell to the ground. The pain continued for three hours and was so severe that he was completely exhausted. The leg then became cold and lifeless. The next day hot packs were applied, the leg swelled, the skin blistered and the tissues turned black and blue below an area extending from the middle of the thigh. A physician was called and a tight bandage was applied covering the whole area. The patient returned to Duluth and entered the hospital on June 16, four days after the onset.

Past History.—The patient had never been sick and had not previously consulted a physician, although he had marked hemorrhoids and an almost complete prolapse of the rectum when first examined.

Examination.—The patient when first seen by me seemed very ill. He was weak and irrational at times. He was quite well nourished. The pulse was 88, temperature 100.2, respirations 20, blood pressure 128/94.

General examination was negative except for the rectal condition mentioned above. The essential pathology centered in the left leg below the knee and extending to the middle of the thigh. The limb below this area was markedly edematous and was blue-black in color. There was superficial sloughing of the skin. There was complete loss of sensation and a motor paralysis in the involved area. No vascular pulsation was noted except in the upper third of thigh.

Treatment.—Preoperatively, this was supportive and included a blood transfusion. A high thigh amputation was performed on June 20, eight days after the onset. Spinal anesthesia was used and outside of another transfusion, the postoperative treatment and course were uneventful.

Pathological Report.—"A fusiform aneurysm of the popliteal artery, measuring 3.2 cm. in diameter and 9 cm. in length. It involved a general dilatation of all the coats of the vessel and all visible orifices of collateral or other branches were obliterated.

"On dissection, the femoral artery for a distance of 16 cm. above the popliteal space contains a friable clot. The walls are markedly thickened and sclerosed. The intima is broken in several places. The sac is filled with a clot organized at the periphery, gray in color. Through its center there is a dark reddish-brown clot, apparently more recent and filling a canalized tube.

"Over the lower two-thirds of the sac, the intima and part of the media is dissected away and peels off with the clot. The wall of the sac measures as much as .6 cm. in thickness. The femoral and popliteal divisions of the vein are closely attached to the aneurysm by dense adhesions. The vessels are all thrombosed in the involved region."

Diagnosis.—Popliteal aneurism with thrombosis.

The possibility of cure, had the patient sought treatment earlier, is doubtful. The blood Wassermann was negative. In this type of fusiform aneurysm only obliterative aneurysmorrhaphy can be performed where the walls are so degenerated (Matas operation). It is improbable that collateral circulation could then be established.

SUMMARY

This case is of interest because the symptoms of the onset were those of an embolus causing complete and immediate obstruction in the popliteal artery. Also, the patient, seventy-four years old, with the usual senile changes, recovered from high amputation of the thigh under spinal anesthesia, an operation which entails considerable shock.

OPINION CONCERNING SAFETY OF SPINAL ANALGESIA

The feasibility of spinal analgesia in surgery was suggested by Corning in 1885 and the first practical application of the method was made by Bier, of Kiel, in 1899. These facts are well known now. Considering the time that has passed since the pioneer work, however, one might expect, concerning the value of spinal analgesia, more unity of attitude among surgeons than seems to exist.

Lundy, whose attitude toward the method has been conservative, writes as follows: "With the close of 1928 it seemed that the severity of the untoward reaction which had been observed previously in spinal anesthesia had decreased, as had the frequency of such reactions, so that the problem which gives the most concern now is that of increasing the period of anesthesia and of retaining safety."

Insufficient duration of analgesic effect is a serious fault, certainly. According to Labat, "one hour is the average time available for operation." Nevertheless, some internationally known surgeons, whose work consists mainly of pelvic operations which they perform as a routine in less than a hour, will not employ spinal analgesia. The reason, perhaps, is that the memory of previous untoward reactions has remained with them and they are not convinced of the safety of the method. Their experience and the responsibility they carry make their opinion worthy of respect. Many anesthetists, however, believe these surgeons to be wrong and they have worked out a number of safeguards which undoubtedly have reduced the hazard.

First of these, in the minds of some, is the experience of the person who administers the anesthetic and whose special care it is, throughout the operation and after the patient has returned to bed, to see that the anesthetic does no harm. More emphasis is placed on experience with some method than on the use of any particular method.

Selection of the drug to be injected has been narrowed considerably by recent experience. Procaine has been widely accepted as having the minimum of toxic effect. Moreover, with the knowledge that has been acquired concerning the use of barbiturates in combating the toxicity of procaine, particularly concerning the use of iso-amylethyl barbituric acid, an added factor of safety is at hand.

In the method of injection are factors of danger or of safety. A needle of medium gauge, preferably of nickel, with a short bevel and with an accurately fitting stylet is used. Formerly, spinal fluid was withdrawn before the analgesic solution was injected. At present, only enough

fluid is taken to dissolve the drug that is used. The injection is made slowly, under only light pressure; in this way diffusion of the solution is prevented and the analgesia is better localized.

Of supreme importance is the position of the patient after the injection has been made. The patient should be placed in the Trendelenburg position and should be kept there for at least three hours after he has been returned to bed. With the head lower than the pelvis cerebral anemia is diminished, and it has been claimed that acute cerebral anemia, rather than diffusion of the analgesic to the respiratory center, is the cause of death during spinal analgesia.

The blood pressure tends to fall in spinal analgesia. Formerly, injection of caffein and strychnine tended to combat this. At present, ephedrine is used with better effect. Lundy is convinced of the value of inhalation of oxygen and of pulmonary ventilation in combating anoxemia, and, in 1928, he reiterated his former statement, "If anoxemia is avoided, death under spinal anesthesia may be prevented."

Now that these factors of safety have come into use and that attention is being directed to retaining safety and to lengthening the period of analgesia, it will be interesting to watch statistics from medical centers of the next few years to see if the proportion of operations under spinal analgesia increases.

R. M. Hewitt, M.D.

SUGGESTED CRIME

Some two years ago the writer commented in these columns upon the contagion of suicide; the serious menace of repeated suggestion lent emotionally unstable folk by the appearance in our news sheets of minute details of suicides, their motives, methods and sequences. A notably conspicuous and ghastly double tragedy has occurred in our vicinity recently, supporting the same contention. Within a few weeks press dispatches from France featured a very unusual trial: an instance of matricide, in which the son shot his mother because of her age, suffering and incurability. A French jury set him free. These accounts were not only featured in the papers, but they were followed up by a series of interviews with notables in various countries, securing expressions of approval or disapproval. Suffice it to say that the jury had enough distinguished support from those who would likewise yield to the young man "the position of judge, jury and executioner"—not to mention temporal control of the divine spark of life—so that they need not have felt lonely on their emotional island.

Thanks to our amazing knitting together of the world, and our ever increasing interdependence, it is difficult to dissociate these newspaper accounts from the northern Minnesota sequel. In brief, it was the shooting to death of a seventeen-year-old victim of a devastating birth palsy —with all its succeeding faulty developments— and the suiciding of an overwrought father. The details can easily be surmised—a helpless child— a thoughtful, indulgent and provident father—a search for causes, remedies, or reasons back of it all—result, futility.

And yet, there were two other lovely children in the family, and a little city full of their equals; why so little glory in the fulfillment of the many because of the grief for the blighted one!

The curtain usually drawn over such a glimpse of the awful potentiality of the human consciousness is that such an act was the result of an unsound mind. The medical opinion will vary, but for the most part it would be a negative one. The irrational mind does not deliver so much courage. It is said that each of us is a personality mosaic, made up out of all our life contacts. These are no longer unit affairs, man to man; the printing press and a thousand agents designed to keep it busy have multiplied the complexity of this mosaic. The press will publish that which is news—always. To those behind the press—who obviously believe so wholeheartedly in advertising and repetition—why is so much repetition used in these suicidal and homicidal stories? Did you notice that recently a long viaduct near Los Angeles was patrolled to prevent an epidemic of jumpers after one had shown the way?

E. L. T.

HISTORICAL COMMITTEE

Medical men have often done many things outside their profession. Many have abandoned medicine for business, some have written poetry and others have entered politics and what not. Who was the President of the United States who studied medicine? Since no president of the United States, so far as I know, ever lived in

Minnesota, you will not find anything about this in our forthcoming book.

To return to the original subject—the man I have in mind entered the army after practising medicine for twenty years, as a Captain of Infantry; was discharged from the service as Brigadier General and then resumed the practice of medicine and followed it for twenty-one years longer.

When your History of Medicine in Minnesota is completed, you may read about him and many others who served in the civil war. Please forward to Dr. Workman whatever scraps of Minnesota Medical history you may be able to supply.

MISCELLANEOUS

UNLICENSED CANCER SPECIALIST CONVICTED OF PRACTISING HEALING WITHOUT A BASIC SCIENCE CERTIFICATE

Boyd T. Williams, owner and operator of a Cancer Sanatorium, at 525 University Avenue S. E., Minneapolis, Minnesota, was convicted October 31, 1929, by a jury in the District Court of Hennepin County, on a charge of practising healing without a Basic Science Certificate. The evidence showed that on or about September 11, 1928, one Mrs. Sophie Weisskirch was operated on at the Williams' Sanatorium for the removal of an alleged cancerous right breast. The evidence showed that on the day previous Mrs. Weisskirch had been examined by Dr. Williams and her ailment diagnosed as cancer.

Previous to Mrs. Weisskirch's going to the Williams Sanatorium, she had received a letter and catalog from Dr. Williams in which she had been informed that small cancers could be cured in a few hours, and large cancers in from seven to nine days.

Mrs. Weisskirch is still receiving medical attention because of the unhealed condition of her body following the above removal of her right breast. She paid Dr. Williams a fee of $300.

The validity of the law was attacked during the trial and also the regularity of the appointments made by Governor Christianson to the Basic Science Board.

The Court overruled the defendant's objections, upholding the law and the appointments of the Board members, the Court's ruling being in direct opposition to the rulings made by the Court in Pope County in the case of State of Minnesota vs. Robert McGraw.

The case attracted quite a number of people and among those present were persons frequently seen at the State Capitol during the 1929 session of the Legislature.

On Monday, November 4, 1929, the Court imposed a fine of $250.

It was disclosed, during the trial, that the defendant was convicted on his plea of guilty in 1913 to practising medicine without a license and was fined $50; also that the defendant was convicted in 1928 on his plea of guilty to a violation of the Basic Science Law, at which time he was fined $100.

The investigation of the case was handled by Mr. Bris on behalf of the State Board of Medical Examiners. The trial and upholding of the Basic Science Law was handled by Mr. Skahen and Mr. Larson of the Hennepin County Attorney's office.

On November 22, 1929, a motion for a new trial was presented to Judge Baldwin in the above entitled matter. Following lengthy arguments and the furnishing of briefs on both sides to the Court, the motion was denied on December 3, 1929.

COMMUNICATION

To the Editor:

Dr. Lewis F. Smead, Chairman of our Board of Trustees, reports that a young man has been traveling throughout the country representing himself as "Lewis F. Smead, Jr., interne at Hopkins." This individual obtained sums of money from Dr. Smead's classmates in Duluth, Minnesota, and Helena, Montana.

Would it be possible for you to run a notice in the Journal of the Minnesota State Medical Association warning physicians to be on the look-out for this imposter? Dr. Smead has no son by the name of Lewis F., Jr. Any help you can give toward stopping this fraud would be appreciated by our Dr. Smead.

Very respectfully yours,

Wm. J. Burns,
Executive Secretary,
The Academy of Medicine,
Toledo, Ohio.

UNGUENTUM CARBONIS COMP. (HILF) NOT ACCEPTABLE FOR N. N. R.

The Council on Pharmacy and Chemistry reports that Unguentum Carbonis Comp. (Hilf) is marketed by the Hilf Products Co., Brooklyn, and that it is claimed to contain an alcoholic extract of crude coal tar, representing from 2 to 2.5 per cent of "its active constituents," menthol and thymol, each 2½ grains to the ounce; eucalyptol, 5 minims to the ounce; salicylic acid, 2 per cent; in a base consisting of kaolin and "boroglyceride" (equivalent to 10 per cent of boric acid). The Council declared Unguentum Carbonis Comp. (Hilf) unacceptable for New and Non-official Remedies because it is a needlessly complex and therefore unscientific mixture, which is marketed with unwarranted therapeutic claims and under a name which is insufficiently descriptive of its composition. (Jour. A. M. A., November 23, 1929, p. 1649.)

President's Letter

DURING the past several years the organization of the Minnesota State Association has progressed amazingly. The effect of this progress has been most noticeable in the field of political prestige, which has in turn excited the admiration of the societies of other states and that of the national association itself. This near spectacular advance has tended to obscure other evidences of constructive work. Therefore the attention of the profession should be drawn to other and no less important activities.

Today we hear much of the menace of state medicine, of the activities of lay bodies in the interest of both public and private health, of free clinics of various sorts, and we ponder upon what is happening and upon our own position in this confusing maze. We find ourselves wondering what the state society may be doing to interpret these many activities and to meet a situation tending possibly to engulf the profession within the meshes of socialism. What is upon us is just this: The public is alive to the importance of both preventive and curative medicine; through its lay organizations it is seeking to promote health and to combat sickness; in its zeal it is apt to work a grave injury to the medical profession, the instrument upon which it leans most heavily for the success of its efforts. We cannot turn this movement back, it is too tremendous, and we would not if we could. It is but a part of the onrush of our civilization.

Our duty is plain. It is to understand the nature and purpose of this movement; to lend wise counsel; to give coöperation in the promotion of that which is good; to exercise, through reason and persuasion, a restraining and guiding influence wherever it may be needed. The state society at this time is so organized as to give this matter proper attention. Through its committees now functioning a great deal is being done. These committees are well calculated to meet the issue wisely and scientifically. Most of our committees overlap in function in some degree and desirably so. Their memberships should interlock. They must function, not as independent bodies, but as a unit. The chairmen of these standing committees must meet, not once, but often. These committees serve as a means of contact between the medical profession and the various public health movements, both official and unofficial. They develop and execute methods of carrying health knowledge to the public and scientific extension service to the profession. Thus these committees promote and correlate our practical business and scientific interests.

Civilization and organization are interdependent. The former falls without the latter while the latter is selfish and oppressive without civilization. Every member of the medical profession in Minnesota should belong to the local, state and national organizations. The strong individualism of the physician has militated greatly to retard professional organization and progress. *But now the time has come when this individualism must be merged with the common interest if the profession is to escape subserviency.* Let all join in enthusiastic effort to fulfill our true function as physicians. We shall be worthy of the admiration of other professional bodies, of the respect and confidence of the people we serve and of our own esteem only as our organized strength and influence are used wisely and for the public good.

S. H. Boyer

President,
Minnesota State Medical Association.

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 10:15 o'clock every Wednesday morning over Station WCCO, Minneapolis and St. Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of January will be as follows:

January 1—"Holiday"

January 8—"The Cause and Prevention of Bunions"

January 15—"Health and Safety"

January 22—"Our Present Knowledge of Infantile Paralysis"

January 29—"Preventable Blindness"

AMERICAN COLLEGE OF PHYSICIANS

The annual clinical session of the American College of Physicians will be held in Minneapolis Monday to Friday, February 10 to 14, 1930. Headquarters will be at the Auditorium.

Monday morning will be devoted to registration and each morning thereafter to clinics by visitors and local physicians at the various hospitals. Scientific sessions will occupy Monday and Tuesday evenings while a convocation and smoker is scheduled for Wednesday evening and a banquet for Thursday evening.

Members of the Minnesota State Medical Association are invited to attend the sessions.

Dr. S. Marx White is chairman of the local committee on arrangements. Special provision is being made for the entertainment of visiting ladies.

The morning clinics are not published in MINNESOTA MEDICINE but the following scientific program scheduled for the afternoons and evenings at the Auditorium gives a good idea of the type of program to be presented.

PROGRAM

MONDAY, FEBRUARY 10, 1930

OPENING SESSION, 2:30 O'CLOCK

1. Addresses of Welcome
   LOTUS DELTA COFFMAN, President of University
   ELIAS P. LYON, Dean of University of Minnesota Medical School.
   EDWARD L. TUOHY, Duluth, President of the Society of Internal Medicine
   S. H. BOYER, Duluth, President of the Minnesota State Medical Association.
   E. L. GARDNER, Minneapolis, President of the Hennepin County Medical Society
2. Reply to Addresses of Welcome
   JOHN H. MUSSER, JR., New Orleans, President of the American College of Physicians
3. Colloids in Medicine
   ROSS A. GORTNER, University of Minnesota
4. Cerebral Localization
   LEWIS J. POLLOCK, Chicago
5. The Psychological Panel in Diagnosis and Prognosis.
   WALTER FREEMAN, Washington, D. C.
6. Gastro-Intestinal Troubles that Now Go Undiagnosed
   WALTER C. ALVAREZ, Rochester, Minn.

EVENING SESSION, 8:00 O'CLOCK

1. Latent Hyperthyroidism Masked as Heart Disease
   SAMUEL A. LEVINE, Boston
2. Observations on the Etiology of Gall-Stones
   A. C. IVY, Chicago
3. The Significance of Atelectasis in Bronchopulmonary Conditions
   FREDERICK T. LORD, Boston.
4. Moving Pictures of the Results of Stramonium Treatment in Encephalitis
   FREDERICK EPPLEN, and (by invitation) A. L. JACOBSON, Seattle

TUESDAY, FEBRUARY 11, 1930

AFTERNOON, 2:00 O'CLOCK

VASCULAR DISEASE

1. The Effect of Generalized Arteriosclerosis upon the Heart and the Systemic Circulation
   GEORGE E. FAHR, Minneapolis
2. Some Newer Aspects in the Problem of Essential Hypertension
   NORMAN M. KEITH and JAMES W. KERNOHAN, Rochester, Minn.
3. The Retinal Vascular Changes in Hypertension
   HENRY P. WAGNER, Rochester, Minn.
4. Arteriosclerosis in Diabetes
   ELLIOTT P. JOSLIN, Boston
5. The Relations of Arterial Sclerosis and Renal Disease
   ALFRED STENGEL, Philadelphia
6. The Causes of Arterial Hypertension
   E. T. BELL, Minneapolis
7. The Management of Hypertension
   JAMES S. MCLESTER, Birmingham
8. The New Possibilities in Classification and Treatment of Anemia
   HILDING BERGLUND, Minneapolis
9. Cinematomicrographic Demonstration of Human Intestinal Protozoa. Pictures and Remarks on their Biology, Pathology and Treatment
   JOHN V. BARROW, Los Angeles

EVENING, 8:00 O'CLOCK

1. History of Syphilis
   JOSEPH L. MILLER, Chicago.
2. History of Certain Medical Instruments of Precision
   LOGAN GLENDENNING, St. Louis
3. Spontaneous Pneumothorax, Non-tuberculous
   F. J. HIRSCHBOECK, Duluth, Minn.

4. The Healing of Tuberculosis, Illustrated by Films and Slides
   Francis M. Pottenger, Monrovia, Calif.

WEDNESDAY, FEBRUARY 12, 1930
AFTERNOON, 2:00 O'CLOCK

1. Splenic Puncture as a Diagnostic Procedure in Infancy and Childhood
   Julius H. Hess, Chicago
2. I. Diagnostic and Physiologic Studies in Certain Forms of Scleroderma
   George E. Brown and Paul A. O'Leary, Rochester, Minn.
   II. Surgical Indications and Operative Results in the Treatment of Vasospastic Types of Scleroderma with Sympathetic Ganglionectomy.
   A. W. Adson, Rochester, Minn.
3. Sympathectomy in Polyarthritis
   Leonard G. Rowntree, Rochester, Minn.
4. The Relation of Experimental Rheumatoid Inflammation to Allergy
   Benjamin J. Clawson, Minneapolis
5. In Defense of the Stethoscope
   James B. Herrick, Chicago
6. Rectal Temperature Curves; Normal and Abnormal
   William B. Breed, Boston
7. The Limitations of Heliotherapy in Pulmonary Tuberculosis
   Bernard L. Wyatt, Tucson
8. Résumé of Our Present Attitude Regarding Iodine in the Treatment of Toxic Goiter
   James H. Means, Boston
9. Unusual Addison's Syndromes
   A. B. Brower, Dayton, Ohio
10. A New Method for the Treatment of Pellagra
    Clyde Brooks, University, Alabama
11. Multiple Polyposis of the Colon
    J. A. Bargen, Rochester, Minn.

EVENING, 8:00 O'CLOCK
CONVOCATION OF THE COLLEGE

The General Profession is cordially invited. No special admission tickets are required.

1. Convocation Ceremony
2. President's Address
   John H. Musser, Jr., New Orleans

The Smoker will follow the Convocation exercises, after a brief intermission. An attractive program has been arranged .

THURSDAY, FEBRUARY 13, 1930
AFTERNOON, 2:00 O'CLOCK

1. Symposium on the Biology of Cancer
   The Etiology and Biology of Cancer
   Leo Loeb, St. Louis
   The Nature of Heredity in Animals
   H. Gideon Wells, Chicago
   Heredity of Cancer in Man
   Aldred Scott Warthin, Ann Arbor
   The Principles of Radiation Treatment
   Francis Carter Wood, New York
2. Undulant Fever in California
   J. Edward Harbinson, Woodland, Calif.
3. Undulant Fever: A Clinicopathological Study
   Walter M. Simpson, Dayton, Ohio
4. Curing the Ulcer Patient
   Seale Harris, Birmingham

The General Business Meeting of The College will be held at 4:00 o'clock in the Auditorium. All Masters and Fellows should attend.

EVENING, 7:00 O'CLOCK
The Curtis Hotel
THE ANNUAL BANQUET OF THE COLLEGE
A Dance will follow the Banquet.

FRIDAY, FEBRUARY 14, 1930
AFTERNOON, 2:00 O'CLOCK

1. Some Observations of Functional Diseases of the Alimentary Tract
   William Gerry Morgan, Washington, D. C.
2. Remarks on Chronic Infections
   Allen K. Krause, Tucson
3. Symposium on the Rôle of Surgery in Pulmonary Tuberculosis
   Pneumothorax
   James Burns Amberson, Loomis, N. Y.
   Pneumolysis
   Ralph C. Matson, Portland, Ore.
   Multiple Intercostal Neurectomy and Phrenicectomy
   John Alexander, Ann Arbor
   Thoracoplasty
   Philip King Brown, San Francisco
   General Considerations of the Rôle of Surgery in Tuberculosis
   Gerald Webb, Colorado Springs
4. The Diagnosis of Pre-Clinical or Latent Tubercle by Caulfield's Inhibitive and the T. C. F. (with Lantern Slides of Chests and Graphs)
   W. E. Ogden, Toronto
5. A Diagnostic Triad in Syphilitic Aortitis
   C. Saul Danzer, Brooklyn

HOUSTON-FILLMORE MEDICAL SOCIETY

The annual business meeting of the Houston-Fillmore Medical Society was held at Rushford, Minnesota, Oct. 24, 1929. A dinner was served at the home of Dr. R. V. Williams, after which an interesting talk was given by Dr. J. M. Hayes of Minneapolis. At the business meeting the following officers were re-elected: Dr. R. V. Williams, president; Dr. G. B. Belote, vice president; Dr. J. W. Helland, secretary; Dr. J. C. Lannin, treasurer; Dr. R. V. Williams, delegate.

The Women's Auxiliary held their annual meeting at the same time.

A vote of thanks was given Dr. Hayes for his talk and to Dr. and Mrs. Williams for the dinner.

J. W. Helland, M.D.,
Secretary.

SECRETARIES' CONFERENCE

The Secretaries' Conference will be held at the St. Paul Hotel, St. Paul, Minnesota, on January 11, 1930, beginning at 9:30 a. m. The conference this year promises to be one of unusual interest and it is important that all secretaries be present. The Lay Health Program of the St. Louis County Medical Society, The Community Hospital and its Original Staff, Malpractice Insurance and its Relations to the Hospital and its Personnel, Storage of *X*-ray Films, Public Health Nursing Standards and the Heart Disease Campaign are some of the subjects to be discussed.

MOWER COUNTY MEDICAL SOCIETY

At the annual meeting of the Mower County Medical Society held December 5 the following officers were elected:

President ..... Dr. J. G. W. Havens, Austin
Vice President ..... Dr. P. A. Lommen, Austin
Secretary ..... Dr. C. L. Sheedy, Austin
Treasurer ..... Dr. A. E. Henslin, LeRoy
Delegate ..... Dr. J. G. W. Havens, Austin

RAMSEY COUNTY MEDICAL SOCIETY

At the annual meeting of the Ramsey County Medical Society held November 25, 1929, the following officers were elected:

Dr. Fred Schuldt—President
Dr. Charles Freeman—Vice President
Dr. Albert Schulze—Secretary-Treasurer
Dr. Frank E. Burch—Member Boeckmann Library Building Fund

SOUTHWESTERN MINNESOTA MEDICAL SOCIETY

The Southwestern Minnesota Medical Society met at Slayton, Minn., Nov. 5, 1929, for their annual meeting. Dr. W. E. Patterson, Westbrook, Minn., was elected president; Dr. E. W. Arnold, Adrian, Minn., vice president; Dr. E. G. McKeown, Pipestone, Minn., Secretary-Treasurer. Mr. F. M. Brist, Saint Paul, was the speaker for the evening.

STEELE COUNTY MEDICAL SOCIETY

The annual meeting of the Steele County Society was held at Owatonna, November 19, Dr. E. J. Nelson, vice president, presiding.

Officers elected for the coming year were:

President ..... Dr. E. J. Nelson
Vice president ..... Dr. J. A. McIntyre
Secretary ..... Dr. A. B. Hart
Treasurer ..... Dr. J. F. Smersh
Censors ..... Dr. E. W. Senn, 1 year
Dr. T. C. Quigley, 2 years
Dr. B. Melby, 3 years

Delegate to the State Medical Association, Dr. A. B. Stewart; alternate, Dr. J. A. McIntyre.

Dr. J. T. Christison, president of the State Association, addressed the Society following the business meeting.

NEW AND NON-OFFICIAL REMEDIES

The following articles have been accepted by the Council on Pharmacy and Chemistry.

CURDOLAC FOOD CO.
- Curdolac Soya Flour
- Curdolac Casein-Bran Improved Flour
- Curdolac Soya-Bran Flour
- Curdolac Breakfast Cereal
- Curdolac Casein Compound
- Curdolac Wheat-Soya Flour
- Curdolac Soya-Cereal Johnny Cake Flour
- Curdolac Soya-Bran Breakfast Food

CUTTER LABORATORY
- Ampoule Solution Silver Nitrate, 1 per cent
- Typhoid Paratyphoid Prophylactic hospital size package
- Polyanaërobic Antitoxin

DE PREE CHEMICAL CO.
- Sulpharsphenamine-De Pree, 0.5 Gm. Ampules
- Sulpharsphenamine-De Pree, 0.9 Gm. Ampules

H. K. MULFORD CO.
- Gelatin Compound Phenolized-Mulford
- Diphtheria Toxoid-Mulford, 30 c.c. vial
- Erysipelas Streptococcus Antitoxin, Concentrated, 10 c.c. syringe
- Typho-Bacterin Mixed (Triple Vaccine TAB), thirty 1 c.c. vial package
- Typho-Serobacterin-Mulford (Sensitized Typhoid Vaccine), 3 syringe package
- Normal Horse Serum without Preservative

NATIONAL DRUG CO.
- Diphtheria Toxoid

THOMPSON'S MALTED MILK CO., INC.
- Thompson's Maltose and Dextrin

TRUTH ABOUT MEDICINES

Digitos Ampules, 5 c.c.—Each ampule contains digitos (New and Non-official Remedies, 1929, p. 138), 5 c.c. H. K. Mulford Co., Philadelphia.

Luminal Capsules, 1 1/2 grains.—Each capsule contains luminal (New and Non-official Remedies, 1929, p. 81), 1½ grains. Winthrop Chemical Co., Inc., New York.

Metaphen 2,500.—It contains 1 part metaphen (New and Non-official Remedies, 1929, p. 272) dissolved in 2,500 parts of water containing 0.33 per cent each of sodium bicarbonate and sodium carbonate. Abbott Laboratories, North Chicago.

Diphtheria Toxoid-Squibb.—This diphtheria toxoid (New and Non-official Remedies, 1929, p. 368) prepared from diphtheria toxin whose L+ dose is 0.2 c.c. or less by treatment with 0.3 to 0.4 per cent formaldehyde. It is tested for antigenic potency by injection into guinea pigs. It is marketed in packages of one immunization treatment of three 1 c.c. vials; in packages of ten immunization treatments of thirty 1 c.c. vials; also in packages of one 30 c.c. ampule. Cutter Laboratory, Berkeley, Calif. (Jour. A. M. A., November 16, 1929, p. 1559.)

A PAGE FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

Report of the Public Relations Committee of the St. Louis County Medical Society

The Public Relations Committee is completing its second year. During this short period it has developed into a committee with more demands on it for service than any other in the society. This has been brought about in spite of the fact that no aggressive attitude has been taken, but rather the committee has stood ready to render service whenever called upon. This proves conclusively that up to two years ago we were passing a golden opportunity to sell a modern scientific medium to the public. No one will argue the fact that information given to the public, through talks and other methods, promotes better health and more happiness. With less preventable diseases, there will be more efficiency and greater production with the general benefit to the whole community. Looking at it from a selfish point of view, it gives us an opportunity to create a greater demand for medical services. Scientific Medicine has much to offer and nothing to hide. Having goods of merit, the better the public is acquainted with, the greater will be the demand for them. We have so many lines that have hardly been touched. The foremost, perhaps, being periodical health examinations.

About one hundred talks have been given to groups and organizations during the past year. Nearly sixty were given during health week last winter. Material was furnished for the "Annual Baby Section" of one of our daily papers, which provoked a very complimentary editorial for us. Speakers have been provided for the "Sixth Industrial Safety School" which was conducted by the Chamber of Commerce last month. The audience consisted of seven to eight hundred foremen and superintendents from Duluth and surrounding towns, who in turn take the message home to the men working under them, so, ultimately, we will reach many thousands.

Work with the newspapers has been rather discouraging. Material presented to them is so badly revamped, it is almost impossible to recognize it in print. Their attitude is changing and they are now calling for material more often, so it is hoped that before long they will be less suspicious that we are looking for free advertising and will be more willing to coöperate.

F. H. Magney, M.D., *Chairman.*

WHAT YOUR STATE MEDICAL ASSOCIATION DOES FOR YOU

1. Publishes the scientific journal, Minnesota Medicine.
2. Creates a Fraternal feeling among physicians and enables them to coöperate with each other in local and state matters.
3. Studies constantly the many changes that are taking place in scientific and economic medicine through the many activities of the committees.
4. Notifies members of current events that affect the profession through Minnesota Medicine, and also sends special communications of unusual, legal, and legislative occurrences.
5. Conducts graduate courses covering the newer aspects of medical practice.
6. Proposes state legislation in the interests of scientific medicine and the public health. It has also been instrumental in defeating many measures which have been proposed to the detriment of scientific medicine and public health.
7. Assists local societies in presenting programs of interest and in securing speakers.
8. Enables its members to secure malpractice insurance at a reduced rate.
9. Conducts an Annual Meeting to which the best medical men in the state and county bring the results of their latest experience and research.
10. Furnishes the members prompt and confidential information on any subject relating to the practice of medicine through the Consultation Bureau.
11. Sends our Legislators *Hygeia* and *Everybody's Health* in order that they may be properly informed on matters of health.
12. Maintains a Speakers Lay Library containing material on subjects suitable to laymen and loans the material to the doctors upon request.
13. Sends weekly health stories to two hundred and sixty rural newspapers.

The welfare of the profession depends upon the support you give it. A well organized profession means greater respect and better compensation.

OF GENERAL INTEREST

Dr. Tom A. Williams, late of Washington, D. C., has returned to Florida from a year in Europe and is now located at the Monterey Apartments, 1611 Michigan Avenue, Miami, Florida.

Leland A. Watson, son of Dr. and Mrs. J. A. Watson of Minneapolis, has been selected as one of thirty-two students in the country to receive the Rhodes scholarship this year. The men elected will take up their studies in Oxford, England, in October, 1930.

Dr. Charles Bolsta of Ortonville, Minnesota, was appointed in December by Governor Christianson to succeed Dr. S. H. Boyer of Duluth as a member of the state board of examiners in the basic sciences. Dr. Bolsta's term of office is for six years, ending April 1, 1935.

The new Community hospital at Detroit Lakes, Minnesota, was opened in December. The new building is a two story structure with full basement and is equipped with 21 beds, placed in 17 rooms. The nurses' quarters are in the basement and consist of a suite of three rooms.

The marriage of Miss Margaret Ritchie of Little Falls and Dr. Asher Abbott White, son of Dr. and Mrs. S. Marx White, of Minneapolis, was solemnized at the First Congregational church in Little Falls, Saturday, December 14. They will make their home in New York, where Dr. White is completing his internship.

The following five University of Minnesota students have been recommended to the medical offices of the United States Army in Washington for internships of one year beginning in July at one of the five Federal Army hospitals in the United States: Norman Anderson, Frank Bacon and Verne Carlson, Minneapolis; Kenneth Ernst, St. Cloud; Theodore Fritsche, New Ulm. Carl Horn of Minneapolis and Robert Hargreaves of Saint Paul were named alternates.

Dr. W. A. Jones announces the termination of his association with Doctor Kittelson. Beginning January 1, 1930, Dr. N. J. Berkwitz will be associated with Doctor Jones. Doctor Berkwitz has been in the department of nervous and mental diseases since 1925 as a teaching fellow and as an assistant and he also was a resident physician at the Boston Psychopathic Hospital for six months. He has recently received a Doctor of Philosophy degree in Nervous and Mental Diseases.

The Eustis Addition to the University Hospital is now open and beds are available for the care of crippled and deformed children who are under 15 years of age. Cases over this age and adults can be taken care of in the General Hospital, where the Orthopedic Division is also functioning. Application for admission to the Orthopedic beds must be made in the same way as for admission to the other services and blanks can be obtained upon request from the hospital.

The Eustis fund provides for not more than 20 free beds, and doctors interested in these should correspond directly with the Superintendent of the hospital. Children who are mentally below the average will not be admitted.

SHORT COURSES IN TUBERCULOSIS SUCCESSFUL

With approximately 140 physicians in attendance and many other applications not accepted because of limitation in size of the classes, the seven short courses in tuberculosis held in Minnesota this fall under the auspices of the Minnesota State Medical Society, the Minnesota Public Health Association, and the various sanatoria were a success, according to the authorities of the various coöperatng organizations.

In addition to lectures by various authorities on tuberculosis, practical demonstrations of tuberculin testing were given. Sanatorium children were given the test previous to the day of the meeting, and examined by the visiting physician for their reactions. *X*-ray pictures were also studied. Medical examinations of patients were made by the enrolled physicians and were checked with the *x*-ray pictures.

Subjects which were discussed included Surgical Complications, Collapse Therapy, Tuberculosis in Children, *X*-ray, Sanatorium Management, History, Gastro-Intestinal Tuberculosis, Sanatorium Care of Tuberculosis in the State, Diagnosis, and Sanatorium Cases.

Among the physicians of the state who spoke at the various short course sessions were Dr. H. L. Taylor, Dr. F. F. Callahan, Dr. E. K. Geer, all of Pokegama Sanatorium; Dr. W. S. Broker, Ottertail County Sanatorium; Dr. Fred Kumm, Fair Oaks Lodge Sanatorium; Dr. L. H. Flancher, Sand Beach Sanatorium; Dr. W. G. Paradis, Sunnyrest Sanatorium; Dr. L. S. Jordan, Riverside Sanatorium; Dr. S. A. Slater, Southwestern Sanatorium; Dr. E. S. Mariette, Dr. F. L. Jennings, and others from Glen Lake Sanatorium; Dr. J. A. Myers, Dr. W. A. O'Brien, Dr. L. G. Rigler, Dr. W. H. Ude, and Dr. C. B. Wright, all of the teaching staff of the University of Minnesota; Dr. Arnold S. Anderson, executive secretary, State Board of Control, Tuberculosis Division; and Dr. George Earl, Chairman, Public Health Education Committee, State Medical Association.

In connection with the majority of the short courses, public meetings were held in the evening and were well attended. A number of the short course staff gave popular health talks at these meetings and also spoke at high school and college assemblies in the towns visited.

Christmas Seal Funds helped finance these courses.

CONSULTATION BUREAU

Wm. A. O'Brien, M.D., *Director*
Minnesota State Medical Association
11 West Summit Avenue
Saint Paul, Minnesota

1. *Question.*—I have a young man, seventeen years old, who had a Wassermann test made a year ago. He received two injections of neosalvarsan at that time. He did not have any other treatment and gradually grew worse. His mind is now affected; he is not able to walk; he is in bed most of the time.
I am giving him neosalvarsan every five to six days. Will you kindly advise me as soon as possible what the latest treatment for syphilis is? Is there any other drug being used besides salvarsan?

   Answer.—I assume from your letter that the original Wassermann test and treatment was done elsewhere. I would advise you to repeat the blood Wassermann and to do a spinal fluid examination. It would also be a good idea to check your neurological findings again. If you are satisfied that he has syphilis with involvement of the central nervous system, the following treatment is suggested:
(1) Tryparsamid once a week for twelve weeks. This is given like neosalvarsan. Start with the one gram dose and increase to three grams.
(2) Follow with six to eight treatments of .6 neosalvarsan every five days.
(3) Then follow with bismuth salicylate in oil every four days or twice a week for twelve weeks. Give one to two c.c. in the hip.
After doing this, we would be very glad to hear from you again and advise you as to the best type of treatment to follow.

2. *Question.*—I would like to find out about the use of typhoid vaccine intravenously in the treatment of arthritis:
(1) What dose should be used?
(2) How many times should this dose be repeated?
(3) For what types of arthritis is this treatment best used?
(4) What advantage has this over the intramuscular injection of boiled milk or other proteins?
(5) What is the theory of its mode of action?
I have a patient, age 29, male, who, I think, would be benefited by this treatment. He has had pain in the left hip, radiating down the leg into the calf of the leg, and sometimes into the instep, since January of this year. It was quite severe until the warm summer months, when, he states, "He could just notice it." This fall, beginning with the cold, the pain has recurred, at times causing loss of sleep and compelling him to do very little, if any, work. He does not have a fever, has not had any redness or swelling of his joints, and the pain is limited to left hip and leg. An *x*-ray of the pelvis was negative. Two suspicious teeth were extracted, and his tonsils were removed with very little, if any, improvement. Please advise me as to the possibility of benefit in this case from the use of typhoid vaccine. This patient has not been benefited by use of salicylates by mouth or intravenously.

   Answer.—Before any further treatment is given, it is best to consider the diagnostic possibilities, and sciatic neuritis should be given consideration. The history of your patient suggests that the nerve may be involved. Is the pain worse on stretching the leg? Is there any atrophy of the calf muscles? Is the Achilles' jerk absent on the affected side? I note that you have had *x*-rays of the pelvis. In a young man with persistent pain such as you have described, osteogenic sarcoma should be considered. We have seen several examples of a long history of pain before the appearance of bone or *x*-ray findings. If you can rule out tumor, and are sure that the joints are not involved, we would suggest using injections of salt solution in the nerve with absolute bed rest and applications of heat before trying protein therapy.

3. *Question.*—There are many lamps on the market at the present time, which are supposed to deliver ultraviolet radiation. How does one gauge the effectiveness of the various types offered to the public?

   Answer.—The best way to compare the various types of lamps is to find out the number of minutes necessary to secure an erythema dose. There is a lamp on the market at the present time, which gives a slight erythema in 45 minutes. This would place it in the harmless class and would be suitable for use in a children's playroom. There is another lamp sold for home use from which an erythema dose can be obtained in 10 to 12 minutes. There is still another in which the erythema dose can be secured in practically the same time as in a physician's office. Before purchasing a lamp it would be best to ascertain the effectiveness of the same by measuring it in the foregoing terms.

4. *Question.*—Would you please send me the treatment for epidemic encephalitis, which is considered the best. If it is the use of neutral acriflavine, please give me the name of the company from which we can get it in the form of ampoules.

   Answer.—We assume that you refer to the chronic stage of epidemic encephalitis. The treatment of the acute stage is the same as the treatment of any other acute disease. We have found that hyoscine hydrobromide in grains 1/100 doses two or three times daily for an adult of 150 pounds gives the best relief of the symptoms of rigidity and tremor. It is true that this is not uniformly successful, but it seems to offer us the best therapy that we have. Neutral acriflavine, in our experience, has not been so successful. We have tried it, however, and intravenous injections can be made. Ampoules of neutral acriflavine may be obtained from any supply house. In any event, it is very difficult to separate the psychic response from real therapeutic result.

OBITUARY

Charles L. Carman

1859-1929

Dr. C. L. Carman, for thirty years a practising physician of Saint Paul, died on the evening of December 13, 1929, at Saint Luke's Hospital, Saint Paul.

Born February 19, 1859, in Kingston, Ontario, Dr. Carman left his home as a young man to study music in New York. When he first came to Saint Paul he taught voice and was very active in musical circles.

A short time after coming to Saint Paul Dr. Carman decided to study medicine and graduated at the University Medical School in 1897. He has practised medicine in Saint Paul ever since, in recent years having specialized in nose and throat diseases.

Dr. Carman joined the Ramsey County Medical Society March 1, 1909, and has been an emeritus member in recent years.

Dr. Carman is survived by one son, Dr. Paul Carman of Saint Paul, and four sisters, Ella and Blanche Carman of Buffalo, New York, Mrs. George Agnew of Mission, Texas, and Mrs. Marcus Simpson, South Glastonbury, Connecticut.

Floyd E. Best

1887-1929

Dr. Floyd E. Best died at his home at Wells, Minnesota, Nov. 9, 1929.

Dr. Best was born Dec. 13, 1887, at Freeport, Ill. He graduated from the Freeport High School in 1906, taking his B.A. degree from the University of Illinois and his M.D. from Northwestern University in 1911. He received his Minnesota license in 1913. His internship of 18 months at St. Joseph's Hospital, Chicago. He also served in hospitals at Los Angeles, Calif., and the Catalina Islands before starting his practice at Wells, Minnesota. During the world war Dr. Best was a first lieutenant in the medical corps, being stationed at Washington, D.C., and later at Humphrey, Va., during the "flu" epidemic. He was graduated from the Army Medical School at Washington, Oct. 25, 1918. Following the war he resumed his practice at Wells, in partnership with Dr. P. F. Holm.

Dr. Best was a member of the Southern Minnesota Medical Association, the Blue Earth Valley, Minnesota State and American Medical Associations.

RESOLUTION OF CONDOLENCE

by the Physicians of the Blue Earth Valley Medical Society.

WHEREAS, the Supreme Ruler of the Universe in His Infinite Wisdom has seen fit to remove from our midst Dr. Floyd E. Best of Wells, Minnesota, an esteemed member of the Blue Earth Valley Medical Society,

THEREFORE BE IT RESOLVED, by the Physicians of this Society,

THAT we deeply regret the passing of a beloved fellow practitioner, because of the unselfish service rendered to his brother physicians and to his patients,

BE IT ALSO RESOLVED, That we offer to his family, their friends and the people of the vicinity of Wells, our most profound and heartfelt sympathy, and that copies of this resolution be sent to the family of the deceased member and to the Wells *Mirror,* and to Minnesota Medicine, Journal of the Minnesota State Medical Association, and be spread upon the minutes of the Blue Earth Valley Medical Society.

(Signed)
Wm. H. Barr, M.D.
P. F. Holm, M.D.
A. J. Henderson, M.D.
Committee.

Olaf Thorstein Sherping

1864-1929

Dr. Olaf Thorstein Sherping died suddenly at 4:15 a. m., December 7, at his home in Fergus Falls. The cause of death was angina pectoris.

Dr. Sherping was born Aug. 6, 1864, in Hallingdal, Norway. He was educated in the high school at Ness, and the University of Christiania. In 1884 he migrated to this country. Here he first worked on a farm, then studied medicine in a physician's office in Wisconsin, and later attended Valparaiso University, where he received the degree of Bachelor of Science. In 1893 he graduated from the Keokuk Medical College. Later he did post-graduate work in surgery in Chicago, New York, London and Vienna.

Dr. Sherping engaged in practice in Enderlin, N. D., from 1893 to 1902. He then moved to Fergus Falls, where he practised continuously until his death.

Dr. Sherping was the founder of St. Luke's Hospital of Fergus Falls, and served as Chief of Staff until 1928. He was a member of the American College of Surgeons, and a former member of the Minnesota State Board of Health.

In 1895 he married Miss May Sollin of Valley City, N. D., who, with his son Ralph, survives him.

His chief interest was in the field of surgery, and from the time when he first performed operations in the sod huts of Dakota until his death, he held a position of notable distinction in his profession.

UNDULANT FEVER

A specific treatment of undulant fever is not yet available. The use of serums has proved disappointing. Vaccines have given more encouraging results according to recent reports from the continent. In particular, an antigen prepared from dried *Brucella abortus* has seemed efficacious in a small number of cases. In this country the use of acriflavine hydrochloride has been suggested to shorten the duration of the disease. (Jour. A. M. A., November 9, 1929, p. 1475.)

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of November 13, 1929

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, November 13, 1929. Dinner was served at 7 p. m., and the meeting was called to order at 8 p. m. by the President, Dr. C. N. McCloud.

There were 35 members and 1 visitor present.

Minutes of the October meeting were read and approved.

A committee consisting of Drs. J. W. Bell, Geo. D. Head, and S. Marx White was appointed to draw up resolutions on the death of Dr. Louis A. Nippert.

The scientific meeting consisted of the following:

Dr. H. A. H. Bouman (Minneapolis) read an historical study of "The Goiter Problem and Theodor Kocher."

DISCUSSION

Dr. Gustav Schwyzer (Minneapolis): We have listened to night to an essay which is the result of an extensive historical study concerning goiter surgery and its founder, Theodor Kocher. Nowadays when thyroid surgery is being done all over the world, it may be timely to bring out the life of the man who did most of the pioneer work in this line.

Dr. Bouman's paper is indeed laudable and commendable. He refers to many of the circumstances of historic interest that surrounded the men who began goiter surgery, and mentions the obstacles these pioneers had to overcome. He calls to our attention Billroth, who was Professor of Surgery in Zurich about 1860-67. I well remember one of his papers on goiter surgery that I read years ago. He reported a small number of goiter cases and of these most of them died from tetany. This mortality rate exceeded Kocher's. The latters success might have been due to his careful way, his method in handling the recurrent nerve and leaving what we call today the safety zone—all such procedures at a time when parathyroids were unknown.

Dr. Bouman's essay does not, in my estimation, call for discussion; however, if you will allow me I will add a few words about Theodor Kocher, with whom I was intimately connected in the nineties. He was a brilliant teacher. His clinics were world-famous. Any one who ever had the privilege of attending one of his clinics could not help being impressed by the magnitude of his knowledge and the accuracy of his diagnosis.

Kocher was not only a brilliant teacher, he was also a great leader as surgeon and writer. Over 200 papers were published in different journals during his activity. He collected the important facts from his material and compiled them into book form for permanent reference. His book on fractures is even today a very commendable work. Another book, which has never been translated into English, on lesions of the spine due to injury or fracture was not only of great surgical interest but an addition to physiology of the spine as well. His work on staphylomycosis and streptomycosis is unique. His book on operative surgery truly expresses the vast wisdom he amassed in his lifetime. There is no phase of surgery wherein Kocher did not do original work.

Always trying to get nearer and nearer the truth, he never missed an opportunity to attend a postmortem examination during his forty-five years of activity at his clinic in Berne.

His endurance for work was simply marvelous, and remained so until his last days. Just two days before he died, in his 74th year, he successfully performed an extensive abdominal operation.

I think we all feel grateful to Dr. Bouman for his interesting review on goiter surgery that he has given us tonight.

Dr. J. T. Christison (St. Paul) reported a case of subacute aleukemic lymphatic leukemia in a young boy, and showed lantern slides.

The patient, a small Canadian boy of 6 years, was admitted to the Charles T. Miller Hospital on September 8, 1929, complaining of a fluctuating temperature, anemia and listlessness.

The child was perfectly well until March, 1928, when he suddenly became ill with a sore throat and high fever. He was confined to his bed for about 5 weeks. His temperature became normal after three weeks' time, when desquamation of the hands and feet was noticed. He had no urinary symptoms, and the father does not recall the child having a cough, nor did he notice a rash. Following this illness the child was pale and listless, but the father was not aware of any elevation of temperature.

Some time early in August, 1929, the mother noticed a marked change in the child. On awakening in the morning he would complain of being very tired and preferred to remain in bed. There was a slight elevation of the temperature at this time and there were noticed black and blue spots over the body, varying in size up to that of a silver half dollar, and apparently spontaneous.

The patient was not a bleeder, although he had had one nosebleed in the latter part of August, which was very mild and lasted only a few minutes.

At the onset of this illness in August the child complained of his legs hurting and seemed to have a painful right knee, at times walking a little stiff.

On September 6, 1929, the child was taken to a hospital in Canada, where the father was told that the child had a very bad heart. He was kept in the hospital one day, receiving no treatment nor medication except aspirin (5 grains every hour for 12 hours). While there his temperature varied from 101.4 to 106 degrees and his pulse from 130 to 148.

The child was then brought to St. Paul and admitted to the Miller Hospital.

Investigation brought out the fact that the child had had no other illnesses except those already mentioned.

He had a tonsillectomy about five years ago, was a breast-fed baby, having been delivered normally.

The child's father and mother, 38 and 36 years of age, respectively, are apparently well, although it was learned that the mother gets very pale at times and has dyspnea on exertion. The father, at the time this history was taken, also looked very pale. One sister, ten years, and one brother, four months, are well, although there is a history of eczema and asthma in these two children. One brother died at thirteen months, of influenza. There is no history of eczema or asthma in the parents or grandparents; nor is there a history of tuberculosis, and it is not known that there were any bleeders in the family.

The father stated that the child passed very large amounts of urine rather reluctantly, complaining of pain. Previous to hospital entry no blood had been noted in the urine.

The child had not been constipated nor had he had diarrhea, and no blood had been noted in the stools.

There had been no swelling of the hands or feet.

A blood transfusion was done on the day after admission to the hospital (Sept. 9) and 500 c.c. of blood given. The patient was classed in Group IV, as was his donor, and the two bloods matched without agglutination. Before the transfusion his blood was: Hb. 23%; red cells 1,550,000; leukocytes 5,350; granulocytes 3%; lymphocytes 97%; and platelets 52,500. After the transfusion his blood was: Hb. 48%; red cells 3,340,000; leukocytes 4,300; granulocytes 4%; lymphocytes 91%.

On September 18 a blood pressure cuff was applied to the left arm and the mercury kept between 95 and 102 mm. The forearm was covered with a light cradle and in six minutes the arm suddenly became covered with small petechial hemorrhages.

On this date he was again transfused, receiving 500 c.c. of blood, the donor this time also being in Group IV and the two bloods matching without agglutination. Before transfusion his blood was: Hb. 48%, red cells 3,340,000; leukocytes 7,750; granulocytes 4%; lymphocytes 93%; and platelets 32,500. After transfusion it was: Hb. 60%; red cells 3,800,000; leukocytes 4,350; granulocytes 4%; lymphocytes 92%; and platelets 97,500.

A consultation by Dr. Connor, of the Nose and Throat Department, disclosed an existing condition of herpes labialis and pale mucous membranes; also a suggestion of thickening of the buccal surface of the gingiva and buccal pads, a scar of a healed ulcer between the upper right first and second bicuspids, and although the tonsils were out there was one small follicle at the base of each fossa. The nose was negative except for pallor and slight septal erosion on each side. There was no sinus infection.

Two weeks later the findings were the same except for the presence of enlarged hemorrhagic follicles in the pharyngeal wall.

On October 4, three teeth were extracted under nitrous oxid anesthesia.

On October 10 the patient was again transfused. He received another 500 c.c. of blood, his donor being classed in Group IV and the two bloods matching without agglutination. This time his blood before transfusion was: Hb. 50%; red cells 2,810,000; leukocytes 6,350; granulocytes 4%; lymphocytes 96%; and platelets 28,000. After the transfusion it was: Hb. 68%; red cells 3,750,000; leukocytes 8,050; granulocytes 5%; lymphocytes 95%; platelets 24,000.

Examination on October 22 showed a petechial rash over the lower extremities and mucous membrane of the mouth. A general reticulo-endothelial proliferation was seen. All glands were moderately enlarged and somewhat hard. At the costal margin the spleen was felt to be somewhat enlarged, though not of lymphatic leukemic type. The liver was also felt at the costal margin.

On October 24, under nitrous oxid anesthesia, several small lymph nodes were removed from the right axillary region. The largest of these was about 5 millimeters in diameter. Microscopic examination showed the prominent feature of the sections to be the diffuse infiltration of large lymphoid cells throughout the nodes, which obliterated the sinuses. The capillary endothelial cells were swollen and prominent everywhere. Diffuse hemorrhage was noted in some areas. The reticulum fibers and reticulum cells were prominent in some parts. The capsules were apparently unbroken. One showed a thickening, edema and hemorrhage and invasion of lymphoid cells into it. A diagnosis of leukemic infiltration of the lymph nodes was made.

At this time the child complained of slight pain in his right knee, especially when the leg was fully extended. There was no apparent swelling, redness or papable tenderness, and measurements of the knees were found to be exact.

Subsequent examination at this time showed the lower edge of the spleen palpable at the left lower costal margin although abdominal distension was so marked as to make palpation unsatisfactory.

During the patient's hospitalization his temperature varied from 98 to 105.4 degrees, and his pulse from 80 to 160.

All urine examinations were negative.

On September 13 his bleeding time was 3 minutes and 20 seconds, and his clotting time 5 minutes and 25 seconds. On October 23 his bleeding time was 5 minutes, and his clotting time 6 minutes and 10 seconds.

Hemoglobin ranged from less than 20% to 70%.

Leukocytes ranged from 1,200 to 12,800.

Red blood cells ranged from 890,000 to 3,990,000.

Reticulocytes from .04% to .3%.

In Schilling Differentials, granulocytes varied from 0 to 6% and the lymphocytes from 90% to 100%.

Platelets varied from 97,500 to 10,000.

Widal was negative.

Blood culture was negative after four, seven, ten, twenty-one and thirty days' incubation.

Blood smear showed 97% lymphocytes. Lymphocytes were of usual mature types with normal variations in size. One per cent were immature or lymphoblast type, a common finding in cases with a marked lymphocytosis. The changes in the red cells are slight for the

grade of anemia. Slight anisocytosis and slight poikilocytosis was present.

Blood smear was submitted to Dr. Downey of the University of Minnesota for his opinion. He agreed with the hospital pathologist in a probable diagnosis of leukemia, subacute stage.

Morphological study (9/30) strongly suggested subacute aleukemic lymphatic leukemia. The pathologist advised consideration of prolonged chronic infection, also.

Morphological study of smears (10/3) showed appearance of the lymphocytes to indicate many of them were pathologic. Nuclei showed a fine, delicate, more or less homogeneous chromatin network and little condensation. In a few, one or more nucleoli were noted and occasionally they were lobulated (questionable Reider type). A narrow zone of dark dirty blue cytoplasm was noted. Apparent absence of cytoplasm in some was not due to staining reaction. A few more mature large lymphocytes showed a wide zone of bluish hyaline cytoplasm in which a few azure granules were seen. Gumprechet shadows were not seen. The red cells showed little polychromasia, if any, and no basophilic granular degeneration. Platelets were very scanty. Granulocytes were less than 10 per cent of cells. Myelocytes, metamyelocytes and older metamyelocytes (band form) were recognized as much as the fully mature neutrophiles, but they were very scarce. Basket cells were seen occasionally. Of course there were many fully mature lymphocytes and occasional plasma cells.

Microscopic examination of the feces showed no red blood cells, leukocytes, parasites or ova. All the usual qualitative tests for urobilin were positive.

Culture of the teeth showed a predominating growth of nonhemolytic streptococci and of staphylococci.

The patient failed rapidly the last week of his life and on the morning of October 29 he had two convulsions, and died of general exhaustion.

DISCUSSION

Dr. Christison: We had an opportunity to observe this entire family. The mother was pale and decidedly anemic in appearance. She was advised to stop nursing the baby. We had blood counts made on the baby, who was left in the hospital for some time, and also on the daughter. I asked Dr. Richards to investigate the mother's condition and he will tell you something about that.

The whole picture from the beginning to end was a hopeless one, as most of these cases of leukemia usually are. An autopsy was done on this boy but we have not yet had time to complete all the studies. I think there will be at least something to add to the pathology of alymphatic leukemia.

Mr. President, I would ask that you call on Dr. Ikeda, who did the postmortem on this case.

Dr. Kano Ikeda (St. Paul) (by invitation): The pathological picture about to be described is not anything unusual, but a typical picture of an acute case of lymphatic leukemia. It is not necessary for me to describe in detail the specimens. I have brought them for you to see. The one striking thing in the external appearance is the waxy pallor of the skin without any emaciation. There were many small petechial spots over the body.

On opening the thoracic cavity nothing unusual was found. The thymus was about 20 gms. in weight, an increase which is usual in this condition. The liver weighed about 1,000 gms., a few hundred grams larger than normal in a child of this age. It was pale orange yellow in color as shown here, and this color is practically the same as when it was autopsied. The spleen weighed 125 gms., or perhaps twice the normal weight. The capsule was dark red and tense, and the cut surface showed a very firm, red pulp. The corpuscles were indistinct. In the gastrointestinal tract, the stomach was very striking in appearance in that there were very many hemorrhagic spots over the mucous membrane. There was hyperplasia of the Peyer's patches in the terminal ileum. The kidneys weighed about 150 gms. (right) and 160 gms. (left) and showed a swollen, waxy parenchyma with areas of hemorrhages in the cortex, as seen in the specimen. There were also some petechial spots in the mucous membrane of the bladder. In a kidney of this kind you would think the function would be impaired. The urea nitrogen of the pericardial fluid showed about 20 mgms. per 100 c.c., which means that probably the function of these kidneys was not particularly impaired. No red cells were seen in the sediments of the urine obtained at autopsy. The lymph nodes, while not very large, were practically every one reddish in appearance with some hemorrhage, so that they are distinctly visualized all along the intestinal border of the mesentery and in the retroperitoneal groups. The bone marrow was hemorrhagic and showed rather solid marrow tissue. The smear made on this, and stained with Wright's stain, shows it to be practically entirely predominated by lymphoid cells. The striking picture found in these specimens is due to a terminal gush of hemorrhage which produced these hemorrhagic spots all over. (Several lantern slides of microscopic sections were shown.)

One thing I want to emphasize is the importance of a careful study of blood smears in cases of this kind, particularly when they happen to be children. This shows us a lesson. When a condition such as this occurs in practice, the ordinary blood counts alone would not be sufficient.

Dr. E. T. F. Richards (St. Paul): The case of the mother is interesting in connection with this child's illness. She gives a history of having been pale and anemic over a period of 12 years, although we could obtain no figures on the degree of anemia. Her age is now 37. She was said to have been particularly anemic at the time this child was born. She has never bled and there have been no other symptoms whatever except the weakness attendant on the anemia. She now shows marked pallor and a very large spleen. There is no generalized adenopathy. Her red cell count is below 3,000,000, Hb. below 40 per cent, with a leukopenia of 4,000, but nothing abnormal in the differential. She has a normal amount of free hydrochloric acid in the gastric contents.

As we do not know the cause of leukemia, one wonders if a particular type of bone marrow insufficiency may have been transmitted by the mother to the child. Then there is, in addition, the infant sister with a profound anemia.

It is a very remarkable coincidence at least, and there may be quite possibly some connection which our studies on leukemia so far have not made clear.

Dr. Walter Ramsey (St. Paul): It is interesting that in these children with leukemia one not infrequently finds a low leukocyte count, which often amounts to leukopenia. One can slip up on them if one is just looking for a leukocytosis. Dr. Stewart had a case of leukemia in the Children's Hospital which never had over 10,000. A high leukocyte count is not necessary in children.

Dr. H. L. Ulrich (Minneapolis) reported a thyroid case complicated with acute rheumatic fever. X-ray films were shown, and postmortem report given.

The meeting adjourned.

Carl B. Drake, M.D.
Secretary.

TRANSACTIONS OF MINNEAPOLIS SURGICAL SOCIETY

Regular Monthly Meeting, Oct. 3, 1929

The meeting was called to order at 8 p. m. in the Hennepin County Medical Society lounge, with an attendance of twenty members and four guests.

The meeting was given over to a discussion of case reports and the presentation of papers.

Dr. Arthur F. Bratrud presented a case of extensive burns on a child twenty months old treated by the immediate application of 10 per cent tannic acid solution. The results in this case were unusually good. No infection had set in and the crust was dry and brown. The child was comfortable within half an hour after the application of the solution as wet packs and has had no pain at any time since.

Dr. Martin Nordland gave the following very interesting discussion of chorio-epithelioma, and showed microscopic slides of his two cases. His paper received a very general discussion by members present.

Chorio-epithelioma is a very malignant tumor, arising invariably in connection, either immediate or remote, with pregnancy. The subject is one of the most debatable chapters in pathology because of the great variation and the frequent lack of coördination between the clinical and pathological findings. In 1910, Ewing made a classification, according to the histology, dividing the tumors into the two main divisions: (1) Benign chorio-adenoma and (2) malignant chorio-carcinoma.

Geist, a later author, believes that there are so many transitional forms between Ewing's chorio-adenoma and chorio-carcinoma that it is impossible to differentiate accurately enough by histological means to be of any prognostic value. Geist's conception seems to be that of the majority of pathologists at the present time.

According to Dr. Bell, the microscopic picture must show invasion of the uterine wall by nests of Langhans cells surrounded by syncytial cells.

In summary, the disease is of fetal origin, therefore in fertile women and located usually in the uterus with a period of latency of a few weeks to several years. Metastasis occurs in nearly all cases through the blood stream, explained by a tendency of the fetal ectodermal cells to erode and penetrate the blood-vessels. The lungs are the most frequently attacked. The vagina and vulva are next in frequently, due to the venous network present. Symptoms are dependent upon whether a uterine tumor or metastasis exists. The most characteristic and prominent symptom of uterine tumor is hemorrhage. Intra-peritoneal hemorrhage (due to a perforated uterus) simulating ruptured tubal pregnancy, is rare. My second case, reported here, deals with such an onset.

There is no uniform treatment. Hysterectomy seems the most reasonable single form of treatment. Radium has not been used enough to warrant conclusions. Partial removal and curettements have cured the disease in some cases and were advocated by Ewing in young women. Prognosis as a whole is bad, recurrence within a year being the rule. There are cases recorded undergoing spontaneous cure.

The first case that I shall report will illustrate Ewing's chorio-adenoma and occurred in a woman thirty-five years of age, whose history is as follows:

Past and family history is essentially negative.

Menstruation began at fourteen years of age and was normal up to seven months before examination. Five normal pregnancies went to term. Miscarriage occurred in January, 1926, following scarlet fever.

The chief complaint had been irregularly recurring menstruation, lasting for periods of six weeks for the past seven months. She had never been quite free from bleeding during that time. She had severe backaches most of the time, felt tired and worn out. Three weeks before examination, the patient noticed a watery discharge with a peculiar pale, pink-colored secretion without odor, for a few days at a time, when the hemorrhage seemed to subside. Patient seemed quite nervous, had a good appetite and slept well. She had not lost in weight.

Physical examination revealed an extremely pale individual, with a dry tongue. Temperature was normal and blood pressure 116/94. Except for a systolic mitral murmur, general examination was entirely negative. Bimanual examination revealed a uniform, smooth painless mass, the size of a large orange, apparently a part of the fundus, filling the cul-de-sac and tilted to the left. It had a cystic feel. The mass was not fixed, could be moved in any direction, returned to the left adnexal region. There was a bloody vaginal discharge. Two weeks later, on re-examination, the physical findings were identical with the previous examination. Patient had a steady bleeding since the first examination. There was no evidence of pain

with the bleeding, such as might be expected with pregnancy.

A diagnosis of uterine myoma was made and hysterectomy recommended.

At operation, the uterus was found to be the size of a grapefruit, corresponding to the preoperative findings, with a dense attachment of the omentum to the left horn. A subtotal supra-vaginal hysterectomy was made.

The specimen proved to be a chorio-epithelioma, grossly and microscopically, the diagnosis being confirmed by Dr. E. T. Bell.

The second case is that illustrating Ewing's chorio-carcinoma with an acute intraperitoneal hemorrhage from uterine rupture. The history is as follows:

A woman, twenty-five years of age, had a history essentially negative except for one pregnancy which went on to term August 3, 1926.

Chief complaint: Last normal period was May 15, 1928. She began to flow July 7, 1928, continued to flow moderately and severely by spells. She was curetted on July 25, 1928, leaving the hospital on July 27. She began to flow again on August 6, with a hemorrhage on the 8th. The patient continued to flow, became anemic, cachectic and extremely weak and on the 6th of September was again curetted. Following this procedure, the patient became much better, apparently regaining her former health, but the regularity of her menstruation was slightly interfered with. An occasional spotting was present. On April 28, nearly one year after the last normal period, the patient was suddenly seized with severe abdominal pain, beginning in the epigastrium and focusing in the right lower abdominal quadrant after about four hours. She had nausea and vomiting. The last regular period was two weeks before this attack of pain. About five hours after the onset, the abdomen was found rigid, with localized tenderness over McBurney's point. A tentative diagnosis of acute appendicitis or ectopic pregnancy was made. The patient was sent to the hospital, where the leukocyte count was 10,000, and a recount two hours later was 10,400. A third count was 9,600.

Bi-manual examination revealed a normal sized uterus in good position. There was some tenderness on examination and pain in the right adnexal region, but no mass was made out.

On opening the peritoneum, free blood was found, filling the interstices between the omentum and loops of the intestine. A snag of omentum was fastened to the top of the fundus of the uterus. The bladder was adherent to the rim of the fundus by recent adhesions and through the bladder fold could be seen an irregular mass, the size of a walnut, projecting on the anterior wall of the uterus. After the bladder was separated away bluntly with the finger, a spurting of bright red blood occurred. This mass was dark brown in color, and about the size of a walnut, projecting under the serosa of the anterior wall of the fundus. The serosa was broken in two places. On the posterior wall of the bladder was an ulcerated surface the size of a dime, with a necrotic base, from which blood was freely oozing. This corresponded to the attachment of the bladder over the mass.

A pan-hysterectomy was performed and the injured bladder repaired. The patient made an uncomplicated recovery.

A diagnosis of chorio-epithelioma was made at operation and confirmed by Dr. Smith and Dr. Bell.

According to Lynch, of the University of California, only nine cases with acute intraperitoneal hemorrhage have been reported.

Dr. Richard R. Cranmer presented the following report of an unusual case of ovarian pregnancy.

The patient is a married woman, aged 32, the mother of two children. No pregnancy has occurred since the birth of her second child five years ago. Menstruation began at the age of thirteen, lasted eight to ten days at twenty-eight day periods. There was no history of dysmenorrhea or pelvic infection.

She menstruated in February, 10 days, as usual, at which time she experienced severe cramp-like pains, especially on the left side. Previous to the menstruation she had had some pain of mild degree on the same side. One week after menstruation she experienced an increasing amount of pain, especially on lifting. She was seen at the office at this time and a mass the size of a lemon was felt to the left of the uterus. This mass was movable, but it gave her considerable pain on manipulation. The temperature was 100 degrees F. by mouth. The leukocyte count was 13,000, red cells 3,800,000, hemoglobin 80 per cent. A diagnosis of ovarian cyst was made and the impression was that it was probably twisted on its pedicle and possibly gangrenous, causing pain and peritoneal irritation, increased white cell count and fever. The possibility of ectopic pregnancy was considered because there seemed to be a slight uterine enlargement but was ruled out because the mass was freely movable and there was no history of a skipped menstruation. No nausea or breast signs had been noted. She was operated upon the following day. The mass was found to be the left ovary without adhesions to any structure. It was dark in color and about four or five times the normal size of an ovary. It was somewhat soft and was taken to be a hematoma of the ovary. It was removed and on opening it was found to contain a sac with clear fluid and what appeared to be placental tissue. A small grayish body was seen on a pedicle, which, I believe, was the fetus, but on looking for it later I could not find it. Dr. Graves sectioned and stained a piece of the tissue suspected of being placental tissue and reported it was placenta. A photomicrographic slide has been made which shows chorionic villi with their two layers, the syncytium and the layer of Langhans cells. The specimen itself was sent to Dr. George Strecter, Director of the Embryology Department of the Carnegie Institute. His report follows:

"I am enclosing photographs of your specimen which prove very conclusively that you have an ovarian pregnancy. In the photographs one can clearly recognize the corpus luteum, graafian follicles and typical ovarian

tissue, embedded in which is the ovum with normal appearing chorion and chorionic villi. The photograph of the gross slide laid open in the midline gives the appearance of the total chorionic sac occupying the central area of the ovary. Around the tips of the villi there is more or less extravasation typical of implantation areas."

Dr. Stanley R. Maxeiner showed two children, both aged six, operated upon for hypospadias by the Bucknall method. Both of these children, up to the time of their operations, had to sit down to urinate. In both instances, the urinary meatus is now at the frenum and both are able to void in the normal manner.

The meeting adjourned.

H. O. McPheeters, M.D.,
Secretary.

PROGRESS

Abstracts to be submitted to Section Supervisors.

Members are urged to abstract valuable articles which they run across in their reading and send the abstracts to the physicians in charge of the respective sections. In order to avoid duplication it would be well to communicate with one of the section supervisors before the article is abstracted.

PATHOLOGY OF SO-CALLED "ACUTE PYELITIS" IN INFANTS: James R. Wilson, M.D., and Oscar M. Schloss, M.D., New York (Amer. Jour. of Dis. of Children, August, 1929, Volume 38, Number 2). Fever and the presence of moderate or large amounts of pus in the urine of infants or young children usually lead to the diagnosis of pyelitis. The authors believe that the usual cause of so-called pyelitis is a true suppurative lesion of the interstitial tissue of the kidney itself.

The frequency with which "so-called pyelitis" follows other infections in the body is suggestive. It seems possible that bacteria may be transported directly to the kidney and excite there an acute inflammatory lesion such as is known to occur in septicemia. This relationship, however, is suggestive only and cannot be considered direct unless the same variety of microorganism is demonstrated as the cause of both lesions.

Postmortem examination showed clearly in their group of cases that pyuria was due to suppurative nephritis, but the clinical picture was indistinguishable from that of so-called "acute pyelitis." Despite the results of postmortem examination, it may perhaps be assumed that pyelitis is the primary disease, with secondary involvement of the kidney. Case 3 is given in illustration.

Case 3.—Marked pyuria in a boy, aged 4 months. Multiple abscesses in one kidney removed at operation. Subsequent enlargement of remaining kidney. Recovery. Left kidney removed and showed an acute suppurative nephritis and a large number of small abscesses. The clinical history of this patient is fairly typical of so-called "acute pyelitis." The persistence of the pyuria and general symptoms following operation, with enlargement of the remaining kidney, strongly suggests that the lesions in both kidneys were identical.

This case demonstrates spontaneous recovery from severe suppurative nephritis and supports similar observations by Forbes, Chown, Bugbee, and others.

The authors believe that the smaller foci which were found in the milder cases of so-called pyelitis are not incidental, but in all probability represent the pathologic lesions which give rise to pyuria.

It is their belief, however, based on the evidence set forth, that the most common cause of severe pyuria in young infants, especially the type of case usually designated pyelitis, is an acute inflammatory process of the interstitial tissue of the kidney.

R. N. Andrews, M.D.

TUBERCULOSIS IN INFANTS UNDER ONE YEAR OF AGE—A STUDY OF THE AUTOPSY AND THE CLINICAL OBSERVATIONS ON INFANTS WITH TUBERCULOUS LESIONS: Katharine Merritt, M.D., New York, New York (Amer. Jour. of Dis. of Children, September, 1929, Volume 38, Number 3). Over a period of thirteen years at the Harriet Lane Home for Invalid Children, autopsies were performed on seventy-five infants under 1 year of age who showed tuberculous lesions.

Ribadeau-Dumas expressed the opinion that a mother with lesions which are becoming progressively worse during gestation can transmit bacilli to the fetus through the placenta.

The views of Calmette and his school, that placental transmission is common, do not seem to be founded on good evidence and are probably incorrect.

In forty-seven tuberculous children under 1 year of age, Hedren found that the bronchial lymph glands were involved in 100 per cent. The lungs were involved in every patient except two. Cavities occurred in nearly 50 per cent of the cases. They occurred most frequently on the right side.

Pleural adhesions were present in nearly 50 per cent of the cases, occurring most frequently on the right side. The spleen was involved in nearly all cases, the principal lesion found being miliary tubercles. The liver, also, was involved in nearly all the cases. The kidneys showed tubercles in more than half of the total number of cases. One-third of the total number of cases in this series showed a definite ulceration of the intestines.

RADIOLOGY OF THORAX: Samuel Brown (Radiology, 1929, XIII, 575). The purpose of this paper is to show the value of studying the thorax in three dimensions. Theoretically, stereoscopy should answer every purpose but this is not the case. Samuel Brown believes after many years of study using stereoscopic plates and supplementing them with a lateral plate that the value of stereoscopy has been over-rated with the exception of an early tuberculosis. But in the case of gross lesions of the cardiovascular and pulmonary system, the anterior-posterior and lateral views are much superior in locating abnormal shadows, determining their relation to surrounding structures and the interpretation of their probable nature.

It has been observed that there exists a constant relation between the size of the thorax and the size of the heart. This has led to the following formula: The transverse and anterior-posterior diameters of the thorax are determined, the measurements being taken at the level of the fourth rib anteriorly. The two measurements are multiplied and the product is divided by the sum of the two measurements. The quotient will be equal to the transverse diameter of the heart under normal conditions. If the actual transverse diameter of the heart, on a six foot plate, does not exceed the predetermined measurement, it will be evident that no hypertrophy or dilatation exists. If, however, the actual transverse diameter of the heart is found to exceed the predetermined measurement, there is strong evidence of the existence of cardiac enlargement.

In the *x*-ray anatomy of the lateral view of the thorax, a glance at the anterior and posterior boundaries shows the anterior costophrenic angle to be on a higher level than the posterior costophrenic angle. Therefore, if a slight amount of fluid is present in the pleural cavity, it is the posterior costophrenic angle that will be obliterated first. The diaphragm may be found to be elevated and partly obscure the heart shadow due to paralysis of the phrenic nerve or increased intra-abdominal pressure. The diaphragm may be pressed low as a result of emphysema, pneumothorax or pleurisy with effusion. Adhesions between the diaphragm and pleura and their exact locations may be determined.

Fine changes in the lung apices cannot be differentiated, but gross changes and their exact location can fully be determined.

The hilus is recognized by its irregular dense shadow below the arch of the aorta. The esophagus cannot be differentiated unless it has been rendered opaque.

In the lateral view, the middle lobe of the right lung overlaps the heart shadow. Tuberculous cavities or infiltrations of a lobe can be located with certainty. The absolute location of a lesion is especially important in diseases of the pleura, such as interlobar empyema and encapsulated empyema.

Thus it is seen that anterior-posterior and lateral views enable one to study the thoracic structures in their true perspective, because one is studying volumes rather than surfaces.

VOL. XIII FEBRUARY, 1930 No. 2

A REPORT OF FOUR CASES OF INOPERABLE CARCINOMA TREATED WITH INTRAMUSCULAR INJECTIONS OF KARKINOLYSIN*

ADOLPH M. HANSON, M.D.
Faribault, Minnesota

KARKINOLYSIN is an extract of the giant epithelial cells of the neck-thymus of young calves.

There is no need of my going into the results in any detail of work done on extirpation of the thymus or of thymus extracts that have been used. The consensus of opinion is that the thymus has something to do with the growth of bone; that it bears some relationship to the genital system in that it is supposed to atrophy after puberty and that castration causes a persistent growth of the thymus, and that its removal causes a hastening in the development of the testes; that it is concerned, especially, in the synthesis of nucleic acid. Achondroplasiac calves have exceptionally large thymic bodies with absence or mere vestiges of the thyroid. The extracts that have been used experimentally have been watery and alkaline extracts, containing the elements of the lymphoid structure and not the true thymus, and contain a large percentage of nucleohistone as similar extracts of lymph glands. This is thrown out of solution by acetic acid.

My supposition, or hypothesis (note that I do not even designate it as a theory), is that the giant epithelial cell of the thymus is the true thymus and that it subserves the function of controlling the correct, normal and healthy rate of epithelial mitosis and cell-division. Another hypothesis that I have considered is that the epithelial cells of the thymus, under certain abnormal or diseased conditions, may get into the lymphatic system and grow again in other locations. However, I have discarded this for the former, as carcinoma takes on the characteristics of the tissue or organ in which it originates: as adenocarcinoma in secretory glands and follicular structures as in the stomach, ovary, etc.

On this basis I decided that the true thymus effect could not be determined unless the lymphoid "muck" could be largely excluded and an extract secured from the giant epithelial cells. In other words: true thymus effect can only be secured when an extract of true thymus is available in a sufficiently concentrated and pure form to render it suitable for use in the treatment of carcinoma in the human. The earliest origin of the thymus is epithelial and it is logical to presuppose that the epithelial elements constitute the true thymus and contain the hormone peculiar to itself.

I have made use of an original method that breaks down the tissue structure of the thymus and excludes the fibrous tissue of the capsule and interlobular structure in addition to a large amount of the lymphoid elements. The extract apparently contains no nucleohistone as no precipitate is secured on the addition of acetic acid. Each c.c. of Karkinolysin (Hanson) represents 0.6 gm. of the fresh gland and has a protein content of about two per cent.

I give it intramuscularly for two reasons: first, because I know that it is effective when given this way; second, because there is much less local reaction and the comfort of the patient under treatment must be considered. It must be given daily in 1 c.c. doses as the lysin effect is best brought about in this way. Perhaps it could be given every twelve hours and in larger doses, but I have secured results by daily intra-

*From the Chemical Research Laboratory, Faribault, Minnesota. Read before the Rice County Medical Society at Faribault, Minnesota, December 11, 1929.

muscular injections of 1 c.c. in inoperable carcinomas involving the peritoneal cavity. This is pioneer work. The dosage is necessarily empirical, but I have found that 0.6 gm. of the fresh gland to each c.c. is about all the extract will hold and produce a clear product with the protein content at about two per cent.

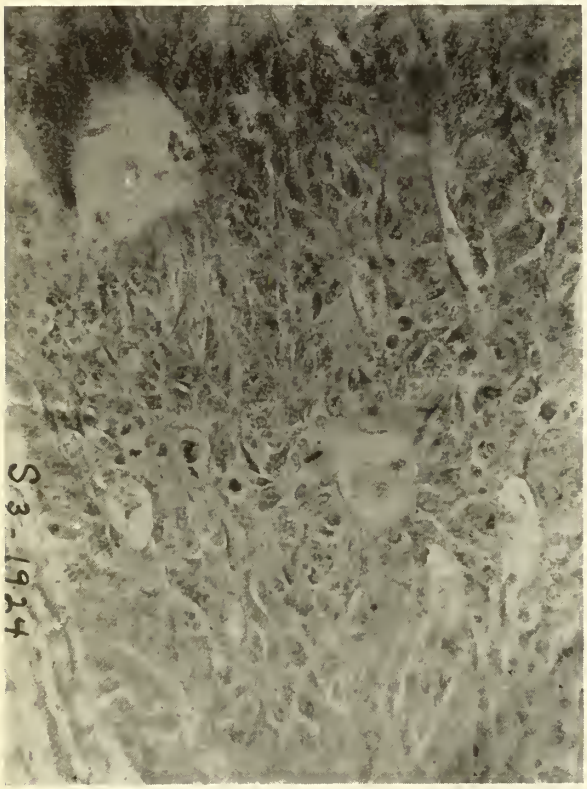

Fig. 1. Microphotograph of the tissue in Case 1, showing the cellular structure.

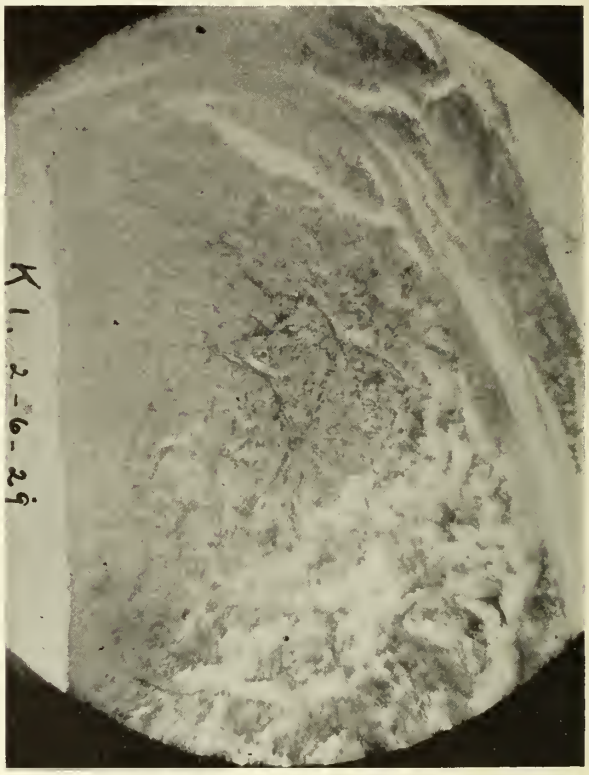

Fig. 2. Low power view of gland removed from patient in Case 2, showing the malignant growth extending beyond the capsule of the gland.

The treatment is carried out by daily intramuscular injections for three to six months, or thirty days beyond the time when all evidence of the disease has disappeared. Such cases must be under the absolute control of the physician, preferably in a hospital.

Engel† emphasizes that in our research on cancer we often consider it as a local affection and overlook the organism as a whole, and yet it is the general condition which determines whether malignant disease may develop or not. Engel relates a report by Rüder of a family in which all seven of the sons developed epithelioma of the skin at ages varying from five months to ten years. There were five girls in this family and all of them escaped such development. Incidentally, the grandfather also had epithelioma of the skin. Of the five sisters, two died of primary carcinoma of the liver which was discovered at autopsy. Attention also is called to the report of Freund and Kaminer that the serum and extract of the organs of cancer subjects do not destroy cancer cells in the same way as do the serum and extracts of organs of the non-cancerous. It has been demonstrated further that this faculty is twenty-one times more potent in the serum of infants than in adults, and this peculiar potency is believed to be connected with the thymus, since the potency declines as the thymus gland retrogresses.

Engel has been experimenting with the protein extracts of various endocrine glands as devised under the methods outlined by Abderhalden, the so-called "optones." He injected such solutions subcutaneously into mice at points remote from the experimental inoculations of cancer. As a result of his work, light is thrown on the potency of these protein products of different endocrine glands and on the influence of the different glands upon the production and inhibition of tumor growth. For instance, it seems that extracts of pituitary tend to promote such

†Engel: Zeitschrift für Krebsforschung, 19:339 (Feb.), 1923.

growths, while extracts of thyroid, and especially the thymus, check it remarkably. The elements responsible for this action seem to be the protein products.

This report led me to consider the possibility

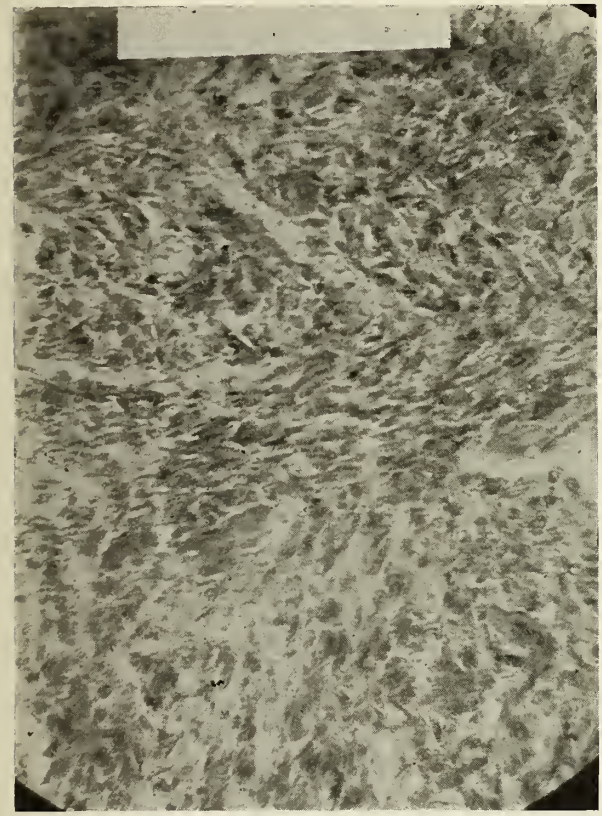

Fig. 3. The general arrangement is shown of the cells in rows in the gland removed from patient in Case 3.

of extracting true thymus activity, and in laying my groundwork for this study I decided to make a histological study of the bovine thymus and to study it grossly in the animal. This was followed by the chemical work in my laboratory which resulted in the production of Karkinolysin, the extract of thymus which has been used in the cases which follow.

CASE REPORTS

Case 1.—Mrs. J. S. White. Married. Age 56.

This woman was brought to St. Lucas Hospital, Faribault, Minnesota, on January 23, 1924, suffering from almost complete obstruction of the splenic flexure of the colon, which became complete, necessitating operation on January 28, 1924. At operation a large annular carcinoma, the size of a clenched fist, was found at the splenic flexure, completely occluding the bowel. It was densely adherent to the surrounding structures and a few enlarged glands were palpable. The transverse colon was fixed in a left inguinal wound and a fecal fistula established forty-eight hours later. On February 6, 1924, my first thymic extract was given intramuscularly in a dosage of 1 c.c.‡

One c.c. was given intramuscularly on the following day, and 2 c.c. intramuscularly every day thereafter un-

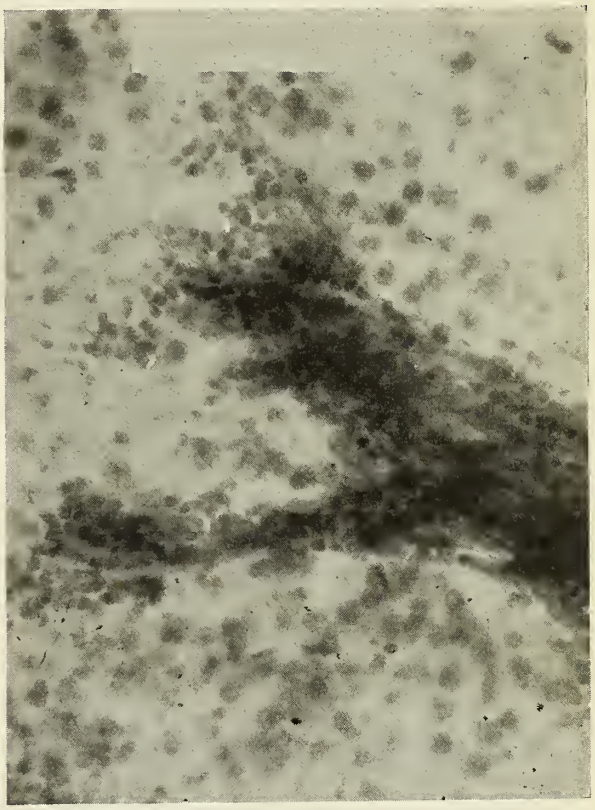

Fig. 4. High power microphotograph, Case 3, showing the end of a trabecula in the gland surrounded by the metastatic epithelial cells.

til February 25, 1924, when the last injection was given. A total of twenty injections were given: 2 of 1 c.c. each, and 18 of 2 c.c. each.

On February 26, 1924, the abdomen was again opened and much to our surprise the mass was much reduced in size, in fact smaller than the circumference of the normal colon, so that it appeared as though a band had been tightly drawn about the bowel constricting it. It was no longer adherent to the surrounding structures and the enlarged glands had disappeared. The splenic flexure, with its hard constricted area, was brought well outside of the abdomen and fixed by interrupted sutures. On February 28, 1924, the loop of extruding bowel was removed by cautery and large clamps applied to re-establish anastomosis.

This patient enjoyed perfect health, with the excep-

‡My first thymic extract used clinically represented only 0.03 gm. of the fresh gland to each c.c. of extract. Even when given in intramuscular doses of as high as 4 c.c., an amount of extract representing only 0.12 gm. was received by the patient. Karkinolysin, a similar extract, represents 0.6 gm. of the fresh glands to each c.c. The fact that results were secured by this crude and weaker extract suggests a hormonal action.

tion of an occasional slight discharge from a small sinus, which persisted at the site of the original fecal fistula, until the illness which resulted in her death from pneumonia in the late spring of 1928. Dr. Theodore Holtan of Waterville, Minnesota, under whose care she was at the time, stated that there was no evidence of recurrence of the malignancy at the time of her death. This

patient received no *x*-ray treatments while in the hospital.

A good stained and mounted tissue section was prepared from a block cut from the gross specimen at the St. Lucas Hospital Laboratory on October 29, 1929. Its description follows:

Splenic flexure of colon 5 years after resection.

Gross Description: The tumor mass is in two parts (bowel divided in its long axis), each consisting of a solid central portion with a short segment of bowel extending out from it in directions nearly at right angles. The solid mass interposed between the two portions of intestinal lumen is fully an inch through. The tissue for examination was a block extending from the open gut into and half way through the solid mass.

Microscopic Description: This tissue on section is seen to be composed largely of hyperplastic abnormal masses of cells, showing clearly basic granular structure. Numerous tubular openings, cut in various directions, are present, lined by columnal epithelium; but these are embedded in irregularly shaped masses of epithelial tissue, clearly malignant in type. Mitoses are abundant. The other portions of the tissue are merely fibrous connective tissue, such as is normally found in connective tissue gland structure.

Summary: Adenocarcinoma.

Case 2.—Mrs. T. J. D. White. Married. Age 42.

This case was diagnosed as carcinoma involving the greater curvature of the stomach by Dr. S. B. Haessly of Faribault, Minnesota, following an *x*-ray examination, and operated upon by him on July 29, 1925.

At operation a large irregular hard mass, the size of a grapefruit, was found in the posterior mid-wall of the stomach, involving the greater curvature and

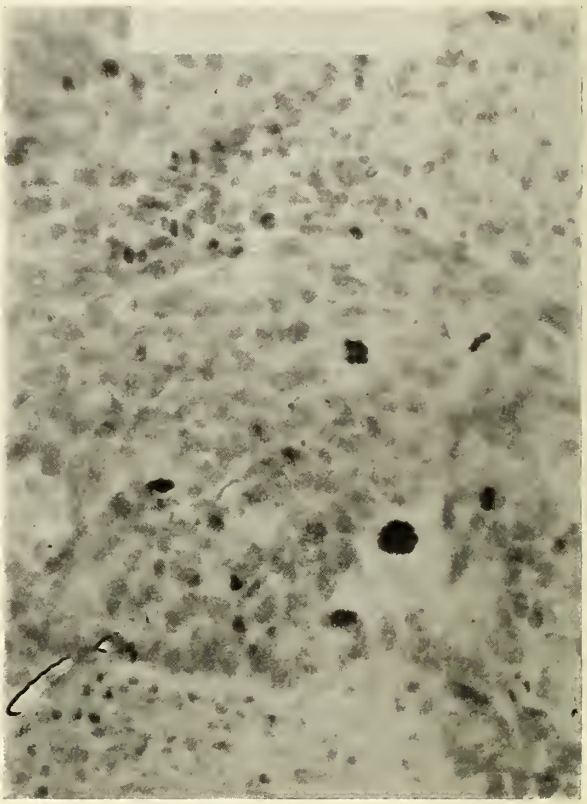

Fig. 6. High power of an area of the preceding illustration, revealing the character of the cells and the active mitosis generally seen through the section.

the lesser peritoneal cavity. The omentum, parietal and visceral peritoneum were studded with widely scattered metastatic growths. A section was removed from the tumor mass in the stomach for microscopic examination.

The tissue at the time was diagnosed from frozen section as adenocarcinoma, but the slide has been lost so I regret that I cannot offer proof of its structure. However, in the light of the other cases reported, it is not devoid of interest.

The record of the injections of my thymic extract given in this case is incomplete. She received the first injection on August 4, 1925. Ten daily intramuscular injections were given in succession, the patient being discharged from the hospital on August 15, 1925. No more injections were given until April 8, 1926, when the patient had gradually become much worse and returned for treatment. From that time, until and including June 12, 1926, she received thirty intramuscular injections in the buttocks, ranging from 3 to 4 c.c., sometimes every day, sometimes three to four days

apart. The tumor mass, eventually, could no longer be palpated. She gained in weight, took on a robust appearance and when last heard from was in good health.

Case 3.—M. A. K. White. Male. Married. Age 35. This man consulted me on December 17, 1928, giving a history of having had stomach and bowel trouble for the last five years. He complained of constipation and

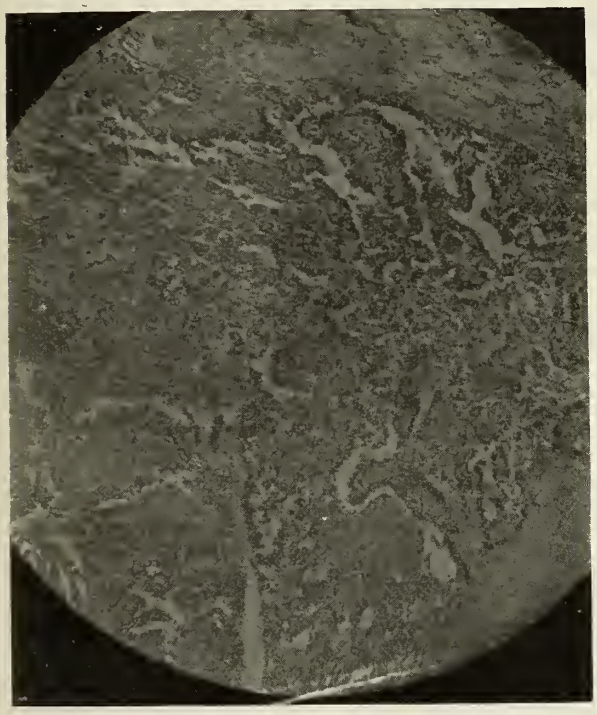

Fig. 7. Relatively low power microphotograph of the metastatic growth removed from patient in Case 4 on June 19, 1929, revealing the papillary growths.

severe cramps in the bowels. He had had obstruction of the bowels two years previous and was very sick. He has had two similar spells since that time, though they were not so severe.

After much study and delay, finding only a spastic condition at the recto-sigmoid junction and a gradually enlarging mass in the left abdomen, an exploratory operation was advised. Sugar in the urine was found on several occasions.

The abdomen was opened by a large left rectus incision on February 2, 1929. A large hard nodular mass, the size of a man's head and half as thick, was found retroperitoneally, extending from the region of the tail of the pancreas along the aorta, to which it was adherent, to the brim of the true pelvis. It was bound down by dense adhesions to the middle and lower thirds of the descending colon. There were palpable glands as large as hazelnuts. One of these glands, densely adherent over the mass, was removed for section and microscopic examination.

Gross Description: A small ovoid mass, about ¾ inch long, enclosed in a fibrous capsule, on section showed a grayish interior.

Microscopic Examination: Microscopically, this showed remnants of typical lymph-gland trabeculæ and a certain amount of lymphoid tissue adjacent to them. The major portion of the interior, however, was made up of larger cells, having epithelial characteristics, densely packed together and in places giving the indistinct appearance of being arranged in rows. The general impression is that of an invasion of lymph gland by metastatic growth of the larger cells which have

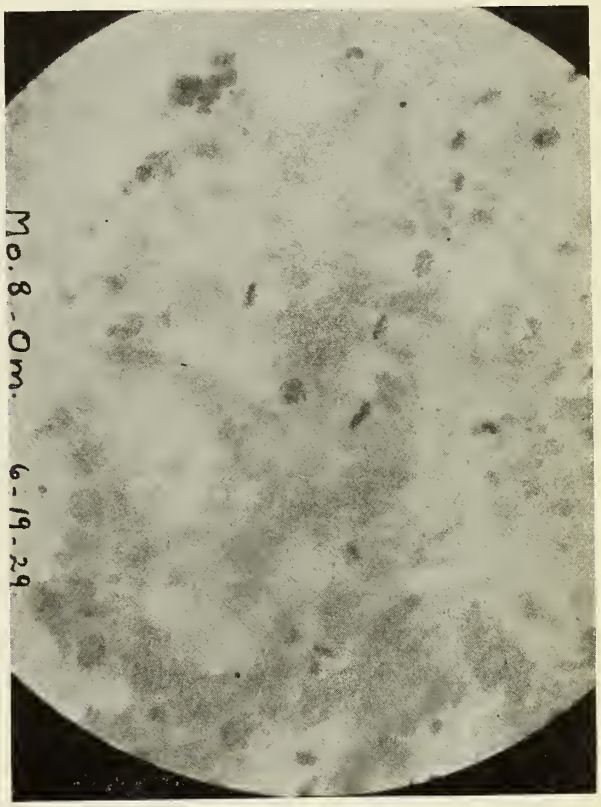

Fig. 8. High power of Figure 7, showing the character of the malignant cells and the numerous and varied mitotic figures.

invaded this gland, but whose source cannot be definitely determined.

Summary: Carcinoma of unknown origin.

On March 4, 1929, he received his first intramuscular injection of 1 c.c. Karkinolysin. From this time to July 26, 1929, he received fifty-one 1 c.c. intramuscular injections of Karkinolysin.

On August 14, 1929, he returned, complaining of pain in the left side of his neck, head and left arm. Large glands could be palpated in the lower posterior triangle of the neck on the left side. A blood examination at this time revealed: R.B.C. 5,440,000; W.B.C. 5,000. Differential Count: P.M.N. 65; lymphocytes 23; mononuclears (large) 5; eosinophiles 1; myelocyte 1; undetermined 5.

On August 26, 1929, he received Karkinolysin 1 c.c. intramuscularly. He did not return until September 21, 1929, when the mass was the size of a large apple and the pain and discomfort was so great that he received no relief from large doses of morphine hypodermically. He could not sleep at night and the pain was almost unbearable.

On September 27, 1929, I made the following notation on his history record: "Metastasis at the site of the thoracic duct emptying into the left subclavian vein." After three daily 1 c.c. intramuscular injections of Karkinolysin, he stated that he could turn over in bed and that the pain was much relieved. After seven injections, on October 4, 1929, the record notes that the swelling in the neck is decreasing rapidly. After fourteen injections, the last on October 17, 1929, he did not return until October 20, 1929. At that time, he stated that he had severe chills on October 18 and thought that he was coming down with the "flu" and did not dare to venture out the next day. His temperature was normal; he felt well and seemed perfectly well on October 20, and the mass in the neck was no longer apparent and barely palpable as a small soft mass, the size of a small hazelnut, behind the left clavicle deep in the neck. The Karkinolysin treatment was continued daily and he is still receiving daily injections.

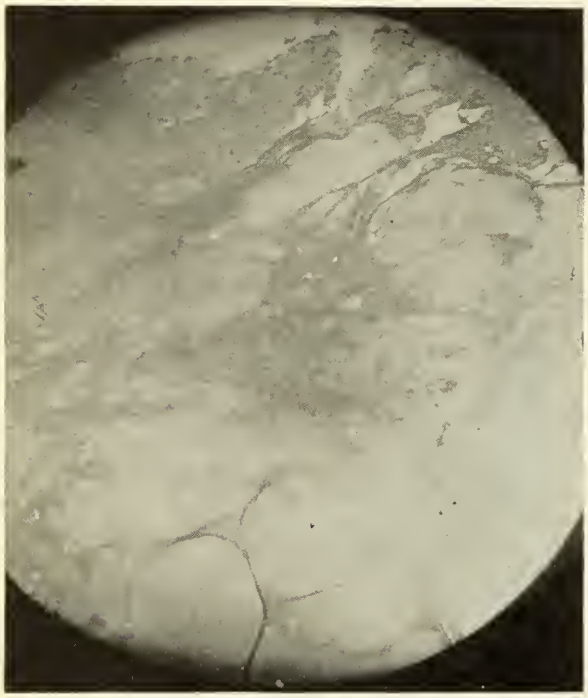

Fig. 9. Low power, showing the general appearance of the tissue from the right ovary removed from patient in Case 4, August 30, 1929.

On March 19, 1929, this man weighed 152 pounds; on July 16, 1929, 157 pounds; on September 29, 1929, 164 pounds; and on October 20, 1929, 167 pounds.

The abdominal tumor is no longer palpable and, at the time of writing this paper, he feels better than he has felt since two months prior to his operation.

Case 4.—Mrs. A. A. M. White. Married. Age 49. This woman consulted me on April 27, 1929, complaining of soreness in the abdomen, heartburn and indigestion—worse last fall and again this spring. Cystitis symptoms were present with a soreness in the pelvis. She had not menstruated since January, 1929, and was very irregular the preceding year. After thorough examinations, a diagnosis of large multiple fibroids was made and operation advised. She was operated upon on June 19, 1929, at which time the gross findings were malignancy involving both ovaries, omentum, and the peritoneum of the anterior abdominal wall and pelvis. Three large metastatic growths were found in the omentum.

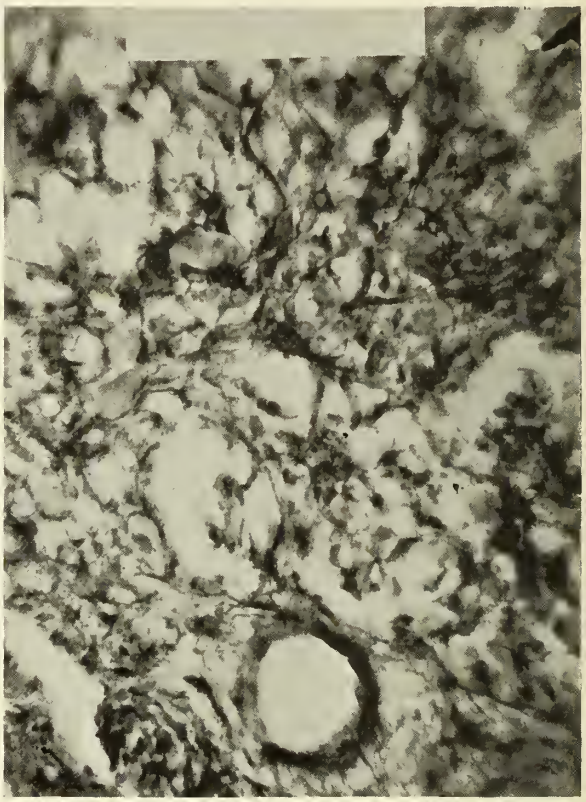

Fig. 10. Appearance of a small area under the high power, showing the general appearance of the tissue and the absence of cellular elements in the right ovary, Case 4.

The right ovary and uterus were so densely adherent over the iliac vessels and in the pelvis that removal was impossible. The large left ovary and one of the metastatic growths in the omentum were removed and delivered to the St. Lucas Hospital Laboratory.

Gross Description of Ovary: Large multilocular ovary containing hard masses and numerous cysts.

Microscopic Description of Two Blocks of Tissue Removed from Left Ovary:

1. This is composed mainly of closely packed epithelial cells surrounding numerous rounded and elongated spaces which are lined by simple columnar epithelium, not set off from surrounding cells by basement membrane. Many of these spaces contain bood-cells. Others are filled by a substance resembling colloid of the thyroid gland, while still others are empty. Throughout this epithelial tissue, mitotic figures are abundant. This section contains almost no connective tissue, except that along one margin. A thick band representing a part of an enclosing capsule is seen.

2. This section consists of a network of broad bands

of connective tissue, within and between which are spaces only partly filled by epithelial cells which line the spaces, in places as a simple columnar epithelium with a distinct gland-like lumen, in others being filled with piled up masses filling the spaces more or less completely, while in still other places there are distinct papillary extensions from the epithelial wall closely packed. The framework is infiltrated with small round cells in places. In others it appears as essentially normal ovarian stroma.

These various conditions evidently represent various stages in adenomatous transformation towards massive or solid carcinoma. The abundant mitoses and abundant blood supply indicate a high degree of malignancy.

Summary: Rapidly developing papillary adenocarcinoma of cystic ovary.

Gross Description of Metastatic Growth in Omentum: The omentum is greatly thickened (¾ inch thick). The whole surface is covered by masses of fatty tissue about the size of a grain of wheat. When cut open, however, the interior is largely made up of white rounded masses of varying size from that of a pinhead to that of a pea.

Microscopic Description of Section from Metastatic Mass in Omentum: Upon microscopic examination these white masses are found to be cysts more or less completely filled by papillary ingrowths from the walls. The papillary growths are covered by columnar epithelium which is simple lining layers in some, but in older growths is piled up in layers of several to many thicknesses, nearly filling the lumen of the cysts. The mitotic figures are very numerous in this epithelium and the blood supply is abundant.

Fig. 11. Microphotograph under low power showing the appearances of the metastatic growth removed from patient in Case 4, August 30, 1929. Note the large area of myxomatous-like tissue in the center, separating cellular areas.

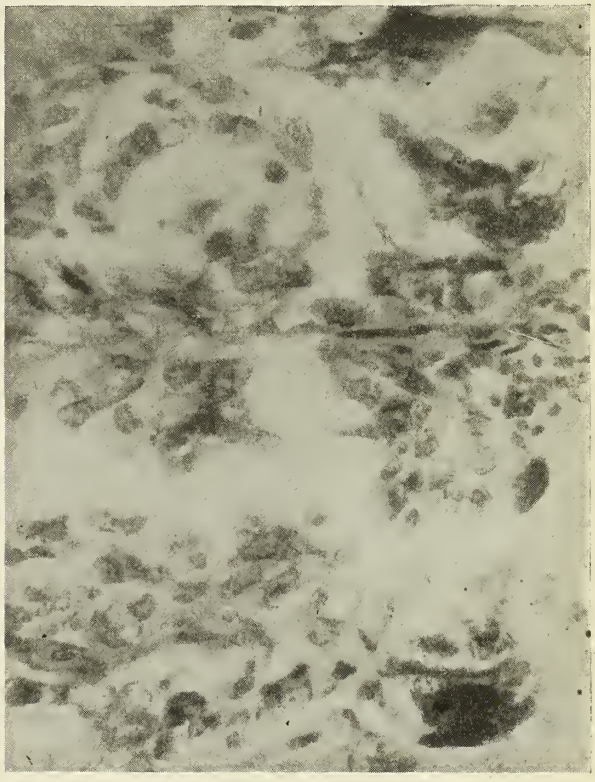

Fig. 12. High power microphotograph of an area of Figure 11, showing the general average appearance of the cellular portions. Note the poor staining qualities of many of the cells and the relatively large areas in which the cells are no longer found.

Summary: The metastatic omental growth is a papillary cystic adenocarcinoma.

The patient in Case 4 was discharged from the hospital on July 4, 1929, and the Karkinolysin treatment was started on July 16, 1929, daily injections being given. On August 2, 1929, the remaining mass was much smaller and she complained of very little tenderness. On this date she received 1.5 c.c. Karkinolysin intramuscularly and her weight was 166 pounds. From that time until August 25, 1929, she received three injections of 2 c.c. each. Her weight on August 25, 1929, was 176 pounds and she felt very well, though she had had several slight hemorrhages from the uterus and the abdomen was rapidly growing larger.

On August 30, 1929, she was again operated upon because of the large cystic right ovary, which was causing increased discomfort in that it distended the abdomen like a large full-term pregnancy. At operation it was found that the large cystic right ovary was completely free from the iliac vessels, except where

densely adherent to the uterus. The adhesions had largely disappared and the two remaining omental metastatic growths, which were left at the first operation in June, were apparently no larger and no evidence of more growths could be found. The glands in the pelvis and the growths in the peritoneum of the anterior abdominal wall had disappeared. The enlargement of the right ovary was entirely due to the formation of more fluid within the cysts, of which quarts were evacuated, and most of the remaining right ovary was removed. At its attachment to the uterus, the uterus was deeply cauterized with the Percy cautery. The two remaining metastatic growths in the omentum were removed with parts of the omentum and with the ovarian tissue were delivered to the St. Lucas Hospital Laboratory. It was necessary to sever the right broad ligament to expose the attachment of the ovary to the uterus.

Gross Description of Tissues: Masses of right ovary in four pieces, which include practically all of right ovary. Two large pieces of omentum. The pieces of ovary are changed so that there is no anatomical resemblance to ovary, but are simply masses of white tissue. The pieces of omentum each contain a hard mass made up of closely adherent masses of carcinomatous-like tissue and represent areas all the way from the size of a pinhead to the size of a walnut.

Microscopic Description of Ovary: No mitotic figures seen. The spaces previously occupied by epithelial growths are represented by a very loose myxomatous-like tissue. Epithelial cells have disappeared. Blood supply not conspicuous.

Summary of Ovary: Myxomatous-like tissue replacing epithelial tissue.

Microscopic Description of Omental Metastatic Growths: Much epithelial tissue in dense masses showing very little open space between the masses. The papillary framework of the epithelial tissue has largely disappeared, so that the epithelial tissue appears to be nearly solid masses surrounded and enclosed by strings of fibrous framework. Some extravasated blood found between epithelial tissues, which may be the result of trauma. Various degenerative changes in the cells with vacuolization and cell-death. The structure of the nuclei is faint and indefinite. No mitotic figures seen, except in one small area (see slide marked "X") where the cells appear clean cut with well defined nuclei and among which mitotic figures are seen. The small area in this section is in sharp contrast to the rest of the section, and other sections.

The author realizes that the diagnoses of types of malignancy may be questioned by experts in this field, but he hopes that the descriptions of the tissues, with the clinical and operative findings, will offer sufficient evidence of malignancy and the changes which took place after treatment.

In the last mentioned case, the only case in which it was possible to note clinical, operative and pathological findings before and after treatment by Karkinolysin, the significant facts are:

The disappearance of enlarged glands and growths in the peritoneum (also noted in the first case reported);

The arrest of metastasis;

The changes in the original metastatic growths, which are: a breaking down of the malignant cells with vacuolization, fading staining qualities and indefinite nuclei; their replacement by a myxomatous-like, or fibrous-like, tissue; and the almost total absence of mitotic figures, and these only found in one small isolated area, like one remaining machine-gun nest after all the rest of the enemy has been wiped out.

I do not attach great significance to the microscopic appearance of the right ovary (having failed to remove a section from this ovary at the first operation), as it may be argued that malignancy never existed in the right ovary. The same cannot be said about the metastatic omental growths. The fact, however, that this right ovary was densely adherent in the pelvis and to the iliac vessels at the first operation and that these adhesions had disappeared at the time of the second operation is suggestive of malignancy in this ovary, also, and a lysin effect from the treatment.

This last patient had a discharge from the wound for some weeks following the operation and a high temperature. This discharge contained small particles of tissue, possibly from the cauterized area in the uterus. At the time of the writing of this paper she is steadily improving and the uterus is diminishing in size. No more uterine hemorrhages have occurred.

In the first three cases reported, we have only the operative and clinical evidence of carcinoma, with seemingly pronounced benefit in two of them, the tissue evidence of one of them being lost. In two of them we have the pathological tissue as evidence of carcinoma.

The last two cases are too recent to state the condition three to four years following treatment, but the tissue studies in the last case, before and after ten weeks treatment, are significant. The microscopic examinations of the tissues removed at the first operation in the last reported case indicate a high degree of malignancy. Whether or not this case becomes eventually apparently cured, or other rapidly growing cases of malignancy will respond so readily, or become arrested in every instance, remains to be seen when nuerous cases have been treated over periods of three to six months, or longer. If Karkinolysin will give relief in only fifty per cent of the cases and prolong life, even if it does not result in permanent cure, it will be a great boon to humanity. In view of the fact that this case was a rapidly growing malignancy of high degree, the findings are only the more significant.

It has been impossible to treat all of the carcinoma patients who have been under the au-

thor's care since 1924 with Karkinolysin. Only the cases of inoperable carcinoma that could be induced to submit to experimental treatment and who stayed by it could be used in this work. After five years, this is all I have to report. The chemical work, which has been the greatest task of all, will not be reported unless it can be shown that Karkinolysin is of as real value as my clinical experience seems to indicate in these four cases. If clinical investigators can duplicate and multiply these results, Medicine will take another step in the right direction. I feel that it is deserving of such a trial, as Karkinolysin is an exceptionally pure extract, with a protein content of only about two per cent. A substance that can bring about such changes in carcinoma as Karkinolysin has accomplished in these four cases deserves our most serious and earnest attention. I do not offer it as a cure for cancer, but as a cancer-solvent, a product that seems to inhibit cancer by breaking down the malignant cells and replacing them by non-malignant issue. The object of my study has been: WHY CANCER? I hope that I am correct in my supposition that cancer is due to a hypothemia, or an athymemia, and that Karkinolysin replenishes this deficiency in the body.

All of these cases received a few deep *x*-ray treatments after leaving the hospital, but the effect was necessarily negligible, especially in the treatment of the abdominal growths, as the *x*-ray machine used was not a heavy duty treatment apparatus, was not capable of carrying a heavy load and no water-cooled tube was available.

SUMMARY

The four cases treated have all shown definite temporary improvement. The treatment seems to cause a necrosis, softening and absorption of at least a part of the tumor. Whether or not a complete destruction takes place has not yet been determined. This may be a partial destruction, as occurs in some cases treated by lead and *x*-rays. That this effect may be due to a foreign protein must also be cosidered.

ACKNOWLEDGMENTS

I am greatly indebted to W. S. Nickerson, M.D., Sc.D., for his study of the pathological tissues reported in this paper; to Sister Amalia of the St. Lucas Hospital Laboratory for the taking of the microphotographs and her assistance in preparing tissue sections; to Dr. S. B. Haessly of Faribault, Minnesota, for consenting to and treating the second case in this series; to Dr. Theodore Holtan of Waterville, Minnesota, for the continued treatment of the last case reported; to E. O. Ellingson, Ph.D., Professor of Chemistry at St. Olaf College, Northfield, Minnesota, for Kjeldahl checks to accurately determine the protein content of Karkinolysin; to Sister Caroline and the Operating Room nurses at St. Lucas Hospital for the autoclaving of my 10 c.c. vials in which Karkinolysin is distributed to clinical investigators and laboratory workers; and to Swift & Company and their Mr. C. P. Kaufmann for their always helpful coöperation in so promptly furnishing me with fresh neck-thymi from young calves for my chemical work.

Hanson, Adolph M.: The Bovine Thymus: A brief description and histological study. Minn. Med., 13:17 (Jan.), 1930.

Note: Other cases are now undergoing treatment by the author and other investigators. If my results can be duplicated, other reports will be made by various investigators regarding its use in the treatment of carcinoma in human beings, as well as its effect in carcinoma in rats. A publication in the near future will describe the method used in the preparation of Karkinolysin.

THE TUBERCULOUS CHILD*

J. A. Myers, Ph.D., M.D.
Minneapolis

THE brightest beacon that has ever lighted the paths of warriors against tuberculosis is our newer knowledge and better understanding of the disease in childhood. Through tuberculosis in this age period we hold the master key to doors that have never been open. We must learn to manipulate the key, otherwise the tubercle bacillus will continue as in the past to deal out destruction and death behind locked doors. The best method of attacking the tuberculosis problem consists of searching for tuberculous children. The following are some of the reasons why childhood is the best age period in life to study and teach tuberculosis:

1. The mind of the child is impressionable.
2. The mind of the child is retentive.
3. Children are gathered together in large groups.
4. Consent for examination is more easily obtained than in later life.
5. The tuberculosis of a community is reflected in the children of that community.
6. Tuberculosis from first infection in the body of a child is often reflected in the lung hilum region even when the initial lesion is in some remote part.

Most tuberculous children can be found by use of the tuberculin test, which, as it is applied to detect tuberculous infection in children, is harmless.

The *intracutaneous or intradermal (Mantoux) test,* because of its greater accuracy and its measure of hypersensitiveness to tuberculin, is the best of all the tuberculin tests. It has become the standard test. The following technic is employed: The surface of the skin where the test is to be applied (the forearm is usually a convenient place) is cleansed with alcohol. An accurately graduated tuberculin syringe containing a solution of old tuberculin of such strength that 0.1 c.c. contains 0.1 mgm. of tuberculin is fitted with a 26-gauge one-half-inch needle. The needle is placed almost parallel to the surface of the skin and is gently inserted into the superficial layers. It must not pass beneath the skin. When the tip of the needle is introduced with the bevel up so the lumen is just out of sight 0.1 c.c. of the solution is slowly forced from the syringe into the skin, where it produces a wheal similar to that seen immediately after applying the Schick test. If there is no reaction in six or seven days the same procedure is repeated but with a solution of such strength that 0.1 c.c. contains 1.0 mgm. of tuberculin. If there is no reaction in six or seven days one may conclude the child is not now infected. When a positive reaction does occur either with 0.1 or 1.0 mgm. of tuberculin, it is usually visible within twenty-four to forty-eight hours after the administration. Occasionally the reaction is delayed. Therefore, when the test is negative we wait approximately one week before applying the second test. There appears a definite deep red nodule which varies in size from one-half to one inch in diameter and surrounding this nodule is a good sized pink halo. This, in extreme reactions, may extend over the greater part of the forearm.

To obtain the proper dilution of tuberculin, take 0.1 c.c. of old tuberculin and add 9.9 c.c. of filtered solution of c. p. physiological saline (0.85 per cent). This is known as dilution A. Of this dilution 0.1 c.c. contains 1.0 mgm. of tuberculin, which is the dose used when necessary to apply a second test. To prepare the dilution for the first test, to 0.1 c.c. of dilution A add 0.9 c.c. of the physiological salt solution. Of this dilution 0.1 c.c. contains 0.1 mgm. of tuberculin. When larger quantities are desired 1.0 c.c. of Koch's old tuberculin to 99.0 c.c. of physiological salt solution gives the dilution for the second test while 0.5 c.c. of tuberculin to 499.5 c.c. of salt solution gives the dilution for the first test. These dilutions should be made fresh every two or three weeks, as they deteriorate. A preservative consisting of 0.33 per cent tricresol or 0.25 per cent phenol may be added. Such preserva-

*Presented before the Ninth Annual Midyear Conference of Wisconsin's Tuberculosis Sanatoria, Lake Tomahawk, Wisconsin, July 6, 1929, the Park Region District and County Medical Society July 10, 1929, and the Scott-Carver County Medical Society of Minnesota August 23, 1929.

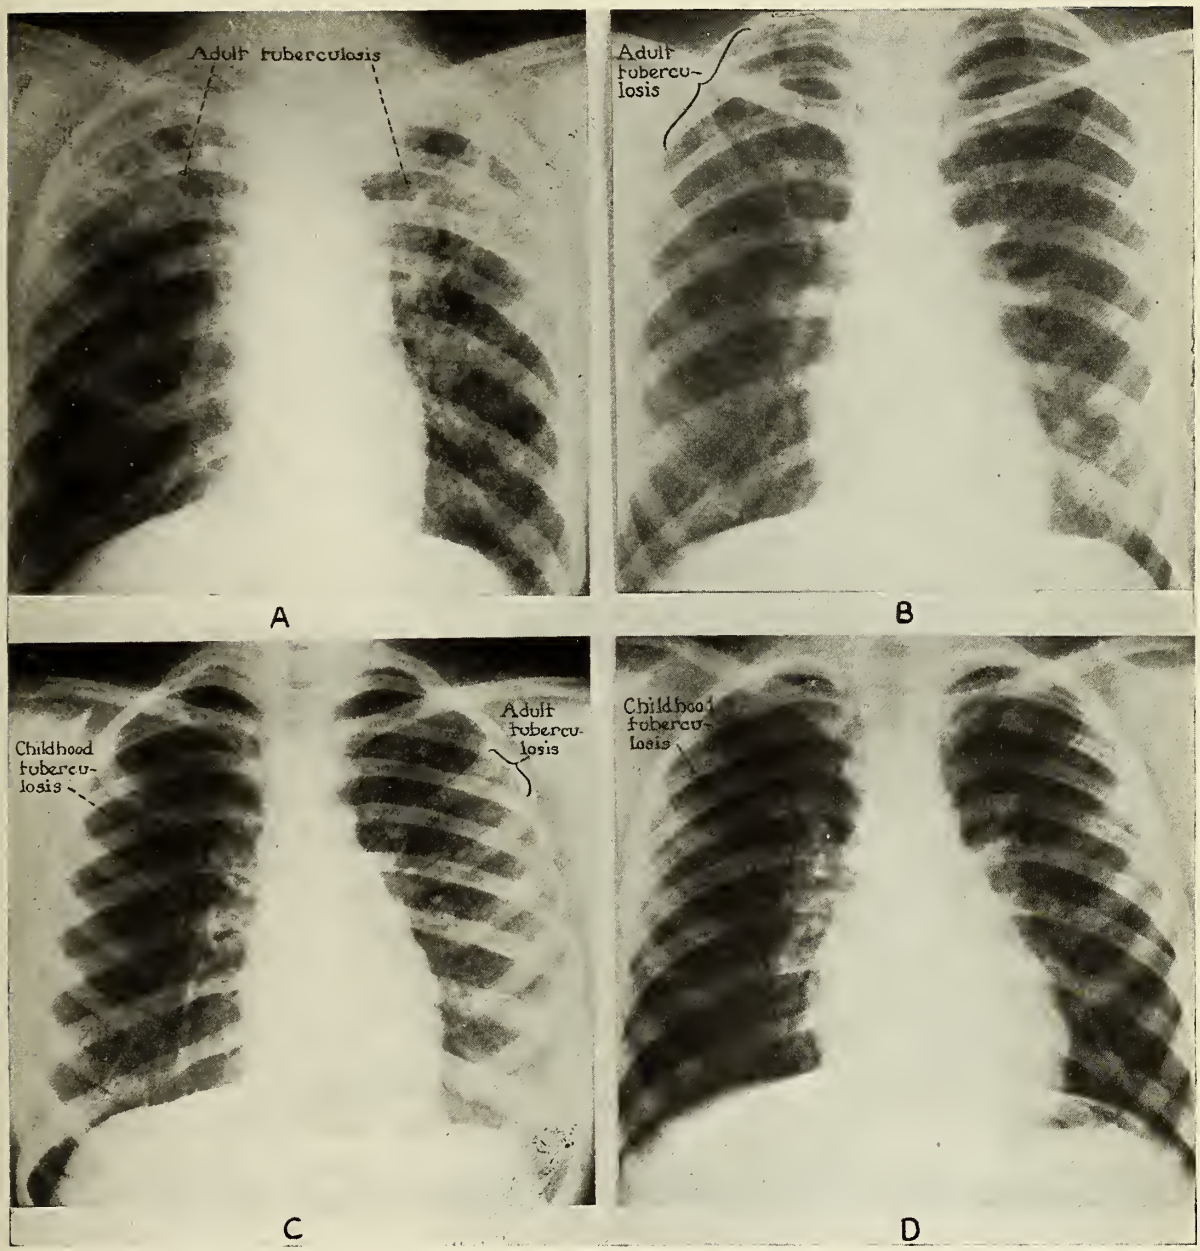

Fig. 1. Roentgenograms of four members of the same family. In 1923 a girl of fourteen years developed pleurisy with effusion. No history of tuberculosis could be obtained. Treatment was refused. In 1925 she died of pulmonary tuberculosis. The source of her infection was still unknown. Inquiry among members of the family revealed the fact that her father had been coughing with a diagnosis of bronchitis since 1920. He was advised to be examined. A few months after the daughter's death he had a frank hemorrhage from the lungs. Examination revealed chronic fibroid pulmonary tuberculosis. Thus the source of the fatal infection was pretty definitely determined through first finding disease in the child. Precautionary measures for the remaining three children were strongly recommended, but not practised. The chest conditions in this family in the spring of 1929 are seen in the illustrations as follows:

A. J. H. Father. Age thirty-nine. Roentgenogram taken May 31, 1929. Advanced bilateral pulmonary tuberculosis, adult type. Not especially ill, but gradually losing in weight and strength.

B. P. H. Daughter. Age sixteen years. Roentgenogram taken June 5, 1929. Childhood type of tuberculosis right hilum. Pulmonary tuberculosis, probable adult type with cavitation right upper lobe. Symptoms present.

C. A. H. Daughter. Age fifteen years. Roentgenograms taken June 5, 1929. Childhood type of tuberculosis in the right hilum. Parenchymal involvement, probable adult type in the second interspace on the left side. No symptoms.

D. M. H. Son. Age eight years. Roentgenogram taken June 5, 1929. Childhood tuberculosis right hilum. Apparently in good condition.

tives cause some precipitation and therefore require that fresh solutions be made every ten or twelve days.

Other tuberculin tests such as the epidermal (Pirquet) and percutaneous (Moro) and their numerous modifications have been extensively used, but the discrepancy between them and the intradermal test has been pointed out so often

that they are rapidly being discarded and the intradermal test has become the standard tuberculin test.

If the epidermal or percutaneous tests are used, there may be an error of approximately 10 per cent. Therefore, to all who react negatively to these tests the intracutaneous test should be applied. All children who react positively should have *x*-ray examinations of the chest. The number requiring this procedure will vary a great deal in different parts of the country and in different sections of the same city. Slater observed that only 10 per cent of the children in a rich rural community reacted positively. Hetherington has found that 72.6 per cent of the children of certain schools in Philadelphia react positively. Chadwick and Zacks report that 11 per cent reacted positively in one section of a city whereas 60 per cent were reactors in another section of the same city. McCain has found 22.7 per cent of the whites and 27.34 per cent of the colored children react positively. In Rathbun's group 41 per cent of the children in the largest city and 25 per cent in the smaller towns of this county reacted positively to tuberculin. Mattill and Fenger have found approximately 22.5 per cent of the school children of small towns and rural communities reacting positively to tuberculin. Frost is finding about 26 per cent of the children with positive tuberculin reactions in a small town in his sanatorium district.

Thus, by first applying the tuberculin test, one reduces tremendously the amount of work necessary with the *x*-ray. In other words, if all children had to be *x*-rayed the problem would be quite insurmountable in many places.

In the earlier days of the study of tuberculosis among school children it was thought safe to select those below the theoretical normal weight, those with some symptoms of disease, and those from homes where tuberculous disease is known to exist, but careful observation has shown that very frequently body weight is not a safe criterion. Not uncommonly the boy or the girl considerably above the theoretical normal weight or even the athlete actively engaged in athletic sports at the time of examination is found to have tuberculous disease. Not infrequently open cases of tuberculosis exist in homes that have been entirely unsuspected. Therefore, there should be no selection whatsoever of cases but an application of tuberculin to all and *x*-ray studies of the positive reactors.

In the past we have been terribly misguided by physical signs. The childhood type of tuberculosis usually causes no abnormal signs. Often this is true even of the adult type. Therefore, many of the clinics that are held are of little value from the standpoint of detection of tuberculous disease in childhood. No one can doubt that the clinic has an educational value, but until we reach the time when tuberculin tests are applied to every child examined and all of the positive reactors have *x*-ray studies, our clinics will continue to be of little value from the standpoint of diagnosis.

What is childhood tuberculosis? It is that disease which results from first infection from tubercle bacilli. In the past we have frequently spoken of it as the primary lesion, as juvenile tuberculosis, puerile tuberculosis, hilum tuberculosis, etc., but the American Sanatorium Association in its recent meeting in Atlantic City placed these terms in the discard and in their stead substituted the term, childhood tuberculosis.

The primary lesion may be in any part of the body. It is often in the lungs. One of the characteristics of childhood tuberculosis is that in addition to producing an area of disease at the point where tubercle bacilli invade the tissues, there very quickly appears involvement of the lymph nodes, draining lymph from that area. For example, if tubercle bacilli find lodgment in the parenchyma of a lung there will usually appear around the focus a definite area of inflammation. This may be small or it may be large enough to involve a whole lobe. Very quickly after the focus appears in the lung definite changes occur in the hilum and tracheobronchial lymph nodes on the same side. Careful *x*-ray studies will frequently reveal them. If the infection has been massive and exposure prolonged the childhood type of disease in the lung may go on to cavitation and even to fatal termination. The disease in the lymph nodes of the hilum and in the tracheobronchial nodes may also continue to progress until tubercle bacilli in large numbers find their way into the blood stream and the child dies of generalized tuberculosis.

Such, however, is not the rule in childhood. There is a strong tendency for childhood tuberculosis to heal so that as time passes the

parenchymal involvement which was surrounded by an area of inflammation shows a gradual decrease of the inflammatory process until it may completely disappear as far as *x*-ray shadows are concerned, or it may take on deposits of calcium or even may become surrounded by true bone so that by *x*-ray examination a dense shadow is cast by this small focus which we frequently speak of as Ghon's tubercle.

The tracheobronchial and hilum lymph nodes may show evidence of calcification in a very short time—five months or less, or they may remain caseous with no evidence of calcification for years.

By any phase of the examination of the living body which we know at present it is impossible to determine when the disease in the lymph nodes has completely healed. Therefore, they may be a potential danger to the child for a long time. We occasionally see such patients who are doing splendidly but who very suddenly develop generalized tuberculosis and die a meningitic death.

If the child survives it, and many of them do, some immunity or protection against tuberculosis is conferred. In other words, people who have had such disease and later develop tuberculous disease will suffer from the chronic adult type. The immunity usually is not sufficient to completely protect against massive and prolonged exposure; therefore, the child who has suffered from childhood tuberculosis should be protected from such exposure throughout the remainder of his life. This applies even to old age. If prolonged exposure is permitted the adult form of tuberculosis often develops. It usually makes its appearance in the upper part of one or both lungs. It is chronic largely because of the partial immunity which has been conferred by the childhood tuberculosis. This immunity results in a fixing of the tubercle bacilli wherever they find lodgment in the body. In other words, they remain, for the most part, in that place and are not rapidly swept off to the regional lymph nodes. Indeed, these nodes usually do not become involved in the adult type of tuberculosis. One sees rather frequently tuberculosis in the adult involving the upper lobe on one side with no involvement of the hilum or tracheobronchial lymph nodes in a patient who has unmistakable evidence of old childhood tuberculosis with a Ghon tubercle and definite calcification of the hilum and tracheobronchial nodes on the opposite side.

The outcome in such cases of adult tuberculosis will depend upon the continuation of exposure, the amount of immunity and the general resistance or well-being of the body. In general it may be said that the adult type of tuberculosis shows far less tendency to heal than the childhood type. In other words, it is the type that kills.

One point that we must keep in mind constantly is that the childhood type of tuberculosis may develop at any age in life. The person who reaches sixty or seventy years and has not previously been infected with tubercle bacilli but now comes in sufficient contact with them to contract tuberculosis will first develop the childhood type. On the other hand, the infant of one year or less who has had the childhood type of disease and whose exposure to tubercle bacilli continues, may develop the adult and highly fatal type.

Therefore, our great problems in dealing with tuberculosis among children are to stop prolonged exposure, and treat those who have become diseased. Many times the source of the exposure is not known. The best way to find the infected child is by tuberculin testing of all children, and the best way to find those with childhood tuberculosis is to *x*-ray the chests of all the positive reactors. When this is done one may find as many as three or four per cent with this type of disease. Thus there is a considerable discrepancy between the number of tuberculin reactors and those found to have childhood tuberculosis. Careful history usually reveals the fact that those with definite evidence of childhood tuberculosis have had prolonged and intimate contact exposure to the disease. It is easy to understand how children reacting positively to tuberculin but manifesting no evidence of disease by *x*-ray may have changes in the lung parenchyma or the hilum which are not sufficiently extensive to be detected by *x*-ray examination, or are obscured by shadows of the bony framework of the chest, the mediastinum and the diaphragm. Again the focus may be found in the cervical or mesenteric lymph nodes. Then, too, there are many children who receive their infections by casual contact exposure. The exposure may have been very indirect. Rathbun

believes that 75 per cent of the cases of adult type of tuberculosis appearing in the teen ages are recruited from children who previously had definite evidence of childhood tuberculosis. This greatly simplifies our problem for it is obvious that if we will detect childhood tuberculosis and institute the right procedure, we will be able to prevent much of the killing type of tuberculosis among our young adults. What are these procedures? From the childhood tuberculosis cases we must look to their associates for the source of infection. The source may be another school child or even a teacher. It may be a father or mother or some other relative who has died of the disease and hence the source has been removed. It may be a father or mother or some other relative whose disease has not been detected but may be diagnosed (Fig. 1), and the exposure stopped through this simple method. Many times since 1921 such findings have occurred at the Lymanhurst School for Tuberculous Children. By this method of approach we may save not only the child but also the unsuspected contact case, and we may save large numbers of children and adults who would have become exposed had the contact case not been detected.

Once the tuberculin testing and the *x*-ray examination have been completed and an attempt has been made to prevent further exposure our duties have not ended. Every child with a positive tuberculin reaction in whom disease can not be found should be kept under close observation. This applies to children who are studied in large groups, such as school children. The private physician who has a case of tuberculosis in a home such as a father or a mother is not discharging his full duty to the family when he treats that patient alone. Over and over again tuberculosis has been shown to be a family disease. When an open case exists in the family the infection will spread to 60 or 80 per cent of the members of the family, and in some cases as many as 100 per cent of the members become infected. Therefore, it is the physician's duty to apply tuberculin tests to all members of the family and as many of the other contacts as will consent, and carefully examine all who react positively. The child who manifests no evidence except a positive tuberculin test should be carefully examined at frequent intervals.

The Fresh Air School, although the name is bad in the light of present day knowledge, has done a great deal for children in different parts of the world. The first school of this kind was founded in Germany in 1904, and in 1908 a similar institution was dedicated in Providence, Rhode Island. Since that time many such schools have come into existence and from the idea evolved the Fresh Air Class Room. In 1904 and 1908 it was believed that "fresh air" took first place in the treatment and prevention of tuberculosis. Now we know that nature has well taken care of us so far as the chemical constituents of air are concerned even in most rooms where we live and work, and that in the treatment and prevention of tuberculosis air has been relegated to last place among the valuable factors employed. But along with the Fresh Air School idea came other factors in treatment such as conservation of energy and good nutrition. To such schools and class rooms are admitted not only children with tuberculous infection, but also children below par from other causes. We are hoping that the time is not far distant when the Fresh Air School and Fresh Air Class Room has a change of name, but that the work which is being done through them will be increased and continued all over the world. Summer camps for children when properly supervised are doing considerable good although the time spent in them is far too short. The physician in private practice who is assuming the responsibility for the health of the families among his clientele welcomes a school or a class room or even a summer camp where he can recommend that the infected children from his families be admitted for special care.

Another great movement was started with the Preventorium idea. The first institution of this kind in the world appeared in Farmingdale, New Jersey, in 1909. "Its purpose was to prevent the spread of tuberculosis by saving the children of tuberculous parents, removing them from their homes in city tenements, where the danger of infection was very great. It was organized on a broad, non-sectarian principle, to take children between the ages of four and fourteen, absolutely without regard to race, creed, or color." From that beginning many similar institutions have been developed. The people of Minnesota are extremely pround of the Ramsey County Preventorium, which under the medical direction of Drs. H. Longstreet Taylor and Everett K.

Geer has for many years contributed a wonderful service to the good health movement. In this institution are taken girls and boys many of whom have been made orphans by tuberculosis. Others are from families poverty stricken by tuberculosis. These children are taken into this splendid institution before they are definitely ill and while they are still good risks from tuberculosis. Special attention is given to the development of their bodies and minds so that many of them overcome their childhood disease and through the school department of the institution are prepared for life's work. This institution has prevented many children from developing the adult type of tuberculosis, exposing large numbers of contacts, becoming a charge upon the city or the county, and finally dying of tuberculosis. Hence the Preventorium idea is also economically sound.

That children tolerate tuberculous infection well if exposure is discontinued has been proved beyond doubt. Even infants will usually overcome it if conditions are good. Among more than 160 infants who were infected at the age of two years or younger, and many of whom are now of school age, we have found through our follow-up work at the Lymanhurst School for Tuberculous Children that only six have died of tuberculosis.

Every child who has developed childhood tuberculosis should have close medical observation, special care to conserve energy and to keep the body in splendid general condition. The child may not look ill; he may not feel ill; he may even be athletically inclined when the evidence is detected, but his diseased hilum nodes or even his parenchymal involvement if in the active stage may result disastrously. Therefore, every case with the childhood type of disease in the active stage should be placed on careful treatment. In the majority of cases the disease rather quickly enters upon a period of latency. This is the period when treatment should continue, but of a less drastic nature than during the period of activity. Latency may be maintained for years; that is, complete healing may not take place for a long time, in some cases even during the lifetime of the individual. Such children need greater care than that provided by the Fresh Air School or Class Room. They need a special institution for tuberculous children. The idea of the first institution of this kind in the world was conceived by Dr. F. E. Harrington, Commissioner of Health of the City of Minneapolis. This institution was dedicated on May 31, 1921, and became known as the Lymanhurst School for Tuberculous Children. It has already served more than one thousand girls and boys. A second school of this kind was founded by Dr. W. P. Shepard and his associates in Berkeley, California, and is known as the Sunshine School. No physician desires to see children among his clientele grow to young adult life only to be stricken down by tuberculosis; therefore, every physician welcomes our newer knowledge and better understanding of tuberculosis in childhood that promises most in the control of tuberculosis.

RELATION OF PHYSICAL FINDINGS TO LUNG PATHOLOGY*

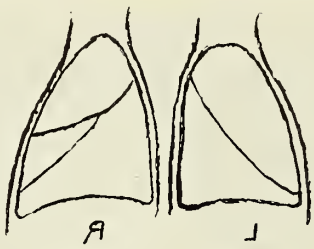
S. H. Boyer, M.D.
Duluth, Minnesota

THE physical diagnosis of pulmonary disorders is far from being an exact science although certainly based upon exact scientific principles. Like many other diagnostic methods it should be considered as an aid in arriving at correct conclusions. So many different conditions may masquerade under such similar physical signs that we frequently find it very necessary indeed to resort to clinical symptoms and history to aid us in making a correct physical diagnosis. So far as pulmonary diseases go it is imperative that we know both normal and morbid anatomy if we expect to make reasonably intelligent interpretations of physical findings.

A short time ago a fellow physician asked me to see one of his cases. He told me the patient was coughing up blood, that it was a lung case of some sort. So of course I went with the lung idea uppermost in my mind. The patient was an elderly man in bed in a semi-recumbent position. He was pale and thin, apparently breathing with some difficulty and frequently coughing up a mouthful of blood. He had been losing weight and strength for over a year and during the year had had at least three colds, as he said, each of which lasted about three weeks. Though the cough on these occasions was productive no blood had been raised. He had been raising blood then for two days.

I observed that the respiratory excursion was greater on his right side; also that the breath sounds were accentuated on this side. Despite the raising of so much blood, rales were conspicuously absent excepting much fine crepitation at the bases. Auscultation did not yield much to indicate any serious lung involvement. Of course pulmonary hemorrhage may arise from a very small lesion, but supposing this to have been a case of active tuberculosis of more than a year's duration we would have expected to have found more than a very small lesion. Percussion also failed to disclose any areas of relative dullness or reduced resonance excepting in the upper portion of the left chest, but this was not marked. All of the lower half of the left chest, front, side and beck, yielded a decidedly tympanitic note. This was so noticeable that I called it to the attention of those present. At once the thought of pneumothorax presented itself, but easily audible breath sounds, accompanied by fine moist râles and a negative coin test quickly dispelled this idea. The voice and whispered sounds and fremitus added nothing suggestive of pulmonary disease. Further examination disclosed a tremendously enlarged heart, with the right border extending well beyond the right side of the sternum. A double aortic murmur was clearly heard, the liver was well below the costal region and the legs were edematous to the knees. The bloody expectoration now took on a new meaning. It was undoubtedly due to a failing heart with pulmonary congestion. The diminished resonance of the upper left chest was due to the crowding of the lung by the enlarged heart. This also was responsible for the limited left chest movement. The tympanitic note in the lower half of left chest was due to a distended colon, a condition, by the way, which sometimes masks pneumonic consolidation of the left lower lobe. The accentuated normal sounds on the right were compensatory. The *x*-ray showed a normal pulmonary picture.

The next case under discussion is that of a man approaching middle life—about forty years old. He was apparently in excellent health when he became ill suddenly. He experienced a pain in his left chest, some difficulty in breathing and a feeling of weakness.



Two days later I saw this patient for the first time. He was in bed in a semi-recumbent position and apparently fairly comfortable, pulse and color good, temperature normal.

His chest was well formed and well developed. One could easily see that the excursion of the right chest was greater than that of the left. Palpation confirmed this observation and also showed tactile fremitus to be dimin-

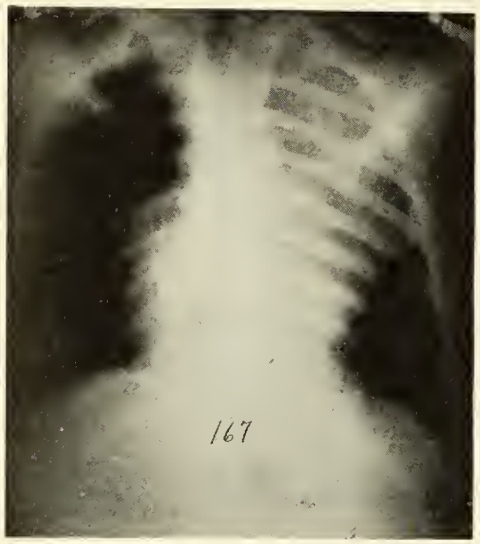
*Read before annual meeting of the Minnesota State Medical Association, Saint Paul, May 15, 1929.

ished over the left chest and increased over the right. Percussion disclosed a distinctly tympanitic note over the lower half of the left chest. This appeared to change toward the back. With the patient sitting bent forward a seemingly dull note was brought out in the interscapular region and over the costal angles. This change was more apparent than real. It was due to the greater thickness of the chest wall in this locality. To one not skilled and experienced in physical signs this is very deceptive. It could easily lead to the conclusion mentioned in the preceding case, namely, that the tympany over the lower left chest was due to a distended colon. Close attention to the note obtained in the interscapular region revealed its tympanitic quality, made distant however by the thicker chest wall. This deceptive relative dullness together with the sharp inspiratory crackling râles present in the same region might suggest a pneumonia or even a pleuritis, were it not for the absence of fever and rapid pulse. Moreover, the breath sounds over all the tympanitic area were distant or absent (with the exception of the interscapular region). Further observation disclosed an absence of heart sounds and apex beat. The heart could not be outlined by percussion because of tympany. During inspiration the intercostal areas between the lower left ribs posteriorly were retracted. The coin test carried its ringing overtones to the auscultator. Here was an undoubted case of pneumothorax judging from the physical signs. The clinical symptoms in association with the physical findings would classify this case as one of spontaneous pneumothorax.

We find various degrees of pneumothorax in various stages of pulmonary tuberculosis. Spontaneous pneumothorax, coming out of a clear sky, occurring in a person who is in perfectly good health so far as any one knows, is in my experience not very frequent. The symptoms are peculiar. There is a sudden sense of smothering accompanied by pain. The pain manifestation is very peculiar. The patient seems to locate it about the precordium, but as he takes a deep breath it seems to shift to the lower chest and to encircle the body. Then he says he cannot tell where it is, by which I judge it to be more or less diffused. The patient's manner is one of great uneasiness and distress. The cases I have seen appear to have great difficulty in finding a comfortable position. They are very restless. I have known this restlessness to continue for upwards of twelve hours. The symptoms are simulated in some degree by artificial pneumothorax. I

Slide No. I. Lobes.

doubt not that the latter type of pneumothorax would be equally distressing, if as large an amount of air were introduced into the pleural cavity rapidly. When the patient takes a full breath, though pain and distress are accentuated, he does so without the halt and intermittance and stitch-like pain of pleurisy. This is quite to be expected for the pleural surfaces are not in contact. Only in case of pleural adhesions being pulled upon by the walls of the distended sac do we expect to find sharp and stitch-like pain.



The sharp crackling râles heard in full inspiration in the case above described are easily explained. The lung is collapsed by the pneumothorax. The contraction of the diaphragm not only fills the lung on the unaffected side with air but in some degree also sucks air into the collapsed lung. The air cells of this lung are closed but dry, hence the sharp crackling as their walls snap apart. Sometimes we hear pleural friction râles quite similar to them but they are neither sustained nor regular. In a pneumonic field they change to a fine crepitation as soon as moisture appears in the air cells.

The following case is one in which the *x*-ray film was shown to me before I saw the patient. The history was of lobar pneumonia, crisis with immediate return and continuance of fever.

The film is a flat picture taken with the bedside unit. A flat picture does not afford any knowledge as to depth, and as no lateral view was at hand the position of the lesion in relation to the front or back of the chest could not

be determined without the aid of physical diagnostic methods.

The left lung is divided into an upper and a lower lobe. The upper lobe is thick above and thins out as it extends downward to end in a thin edge at the level of the sixth rib in front.

Slide No. II. Abscess.

The base of the lower lobe rests on the diaphragm. It thins out as it reaches upward to end in a thin edge behind at the level of the third thoracic vertebra. A line drawn from this vertebra around the side of the chest to the sixth rib in front will mark the line of division between the upper and lower lobes of the left lung.

Lobar pneumonia commonly involves an entire lobe. Therefore an *x*-ray shadow of a pneumonic lobe should show the outline of the lobe affected and should be of greatest density at the thickest part of the lobe. It should fade as the thin edge is approached. The intensity of the physical signs, especially those developed by percussion, palpation and auscultation, should be in conformity.

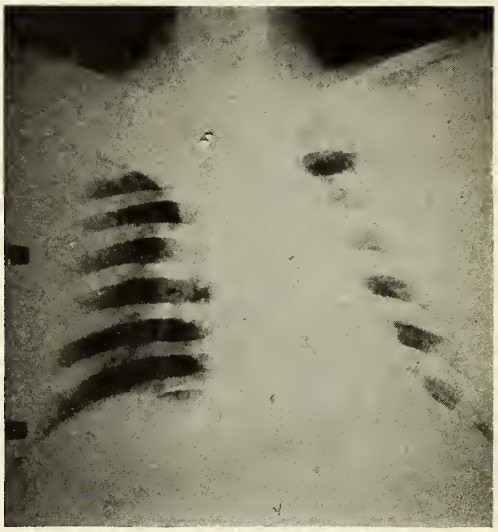
Looking at the film we perceive a shadow of uniform density extending as far down as the sixth rib in front. If it were pneumonia the shadow should show less density below unless a part of the lower lobe also were involved. Again the lower border of the shadow is quite rounded, so much so in fact as to suggest a distribution of the lesion not confined to lobe boundaries. So one thinks of pus.

Turning now to the physical findings: Percussion brought out a flat or dull note from the supraclavicular region to the third intercostal space in front. The dullness abruptly ended there and passed laterally and backward in a horizontal line across the axilla. Posteriorly the flat note in the suprascapular region extended down through the left interscapular space to the angle of the scapula. Laterally the note anterior to the posterior axillary line was resonant. The auscultatory sounds over the flat area were such as are heard in pneumonia only they were very distant. The distribution of the physical signs in this case located the lesion in the extreme upper end of and in the posterior part of the left chest. Upper-lobe pneumonia could be safely excluded. The lesion was too extensive to be a lung abscess. Its position was not in keeping with that of either lobe. The only possible diagnosis in the light of the physical findings was a circumscribed empyema in the upper and posterior part of the left pleural sac.

Some time ago while looking at some *x*-ray films of tuberculous chests I began to wonder what would be revealed by a film of those same lungs without an intervening chest wall. I wondered if the study of the films of the naked tuberculous lungs would be helpful in understanding physical signs. It is not easy to remove lungs in their entirety, at autopsy, without tearing their enveloping membrane at one or more points. As the specimens must be filled with air to make their *x*-ray pictures valuable, such an accident must not happen. One day Dr. A. G. Athens, pathologist to St. Luke's Hospital in Duluth, performed an autopsy on a tuberculous patient who had died of an intercurrent disease. With great skill he succeeded in securing for me, intact, a pair of lungs far advanced in fibrocaseous tuberculosis. I think the film gives as clear a conception of the distribution of the lesions as did the fresh gross specimen. It certainly shows why various signs should, or should not, be found during physical examination.

DISCUSSION OF FILM

Looking at the film one is impressed at once with the tremendous extent of the disease and the wealth of detail. Here we have large and multiple caseation, cavitation, fibrosis and pneumonic infiltration. Some of the small areas



of caseation show dense borders indicating sufficient age to permit fibrotic changes. Others of them are lacking in these borders and undoubtedly represent the more recent pneumonic changes in which the reparative fibrotic process has not had time to develop.

Slide No. III. Lungs.

We may well picture in our mind's eye an emaciated patient with sunken chest walls and shallow breathing. Closer inspection would reveal lost movement in the apical regions of the chest, the reason to be clearly discerned in the large apical cavities. The cracked pot sound ought to be found in the apex of the right lung, unless the bronchi leading from it are occluded. In that case it would most likely be full of matter and dull to percussion. The dense shadow in the right lung below the great cavity is due in part to an area of greatly thickened pleura (as shown at autopsy) and in part to extensive caseation. Here the percussion note ought to be flat behind, where the pleura was thickened, and probably near flat in front. Elsewhere over both lungs there should be decidedly impaired resonance because of the extensive infiltration and caseation. Strangely enough in some of these advanced tuberculous cases the resonance seems not to be impaired, probably because of using heavy percussion. This elicits sound from a large area, so again tympany may influence the quality of the note. Light percussion should be used in these cases.

Auscultation should detect cavernous or amphoric breathing over the large cavity, perhaps distant bronchial breathing or absence of breath sounds over the thickened right pleura

Slide No. IV. Patient's Chest.

behind where it touches upon the great area of caseation. Elsewhere there might be detected many and various degrees of bronchial and broncho-vesicular breathing. It is doubtful if normal vesicular breathing could be found any place in a case so advanced as this one. And what about rales? All kinds I should think, for the tuberculous process is active, and a pus-producing mixed infection must exist in the cavities and bronchi, thus causing moisture.

The functional surface of the lungs has not yet been wholly destroyed though it is greatly encroached upon by the pneumonic process. It is in the pneumonic fields and just bordering on the areas of small caseation that the fine moist râles should be heard. These areas of small caseation, whether pneumonic or fibrotic, should yield broncho-vesicular breath sounds, *i.e.*, inspiratory sound of higher pitch than that of normal vesicular breathing with a lengthened expiratory sound. The voice and whispered sounds should be increased in proportion to the degree of consolidation and its proximity to patulous bronchi.

After seeing this film I couldn't rest until I had an opportunity to review the hospital record of the case and make comparisons. Only

that portion of the record bearing upon the pulmonary condition will be submitted.

This unhappily is not a very good film. Nevertheless it enabled the radiologist to record the following note:

"Massive bilateral pulmonary tuberculosis involving all lobes both lungs. The lesion is a mixed lesion of fibrocaseous type with more or less acute areas.

Signed by
Dr. T. G. Clement."

Observe the tremendous difference in the stories told by these two films. Even if the picture of the chest had been very superior, still the differences would be very great. The skill of the radiologist in his film reading is proven by a glance at the picture of the lungs.

Turning now to the clinical chart the following is recorded:

"Right Lung: Impaired resonance to fourth rib and sixth dorsal spine. Bronchial breathing to first and fifth dorsal spine. Medium coarse râles to third rib and seventh dorsal spine on ordinary breathing and coughing. Left Lung: Impaired resonance to fourth rib and seventh dorsal spine. Bronchial breathing to same area. Coarse râles throughout on quiet breathing and coughing."

I wonder at the paucity of findings in so rich a field. Yet we do not always easily detect all the signs above mentioned, and not without good reason. At least two factors enter into consideration. There is in this case very extensive fibrosis. Fibrosis represents lung destruction quite as certainly as does caseation. Lung destruction means reduced elasticity and shallow breathing. Shallow breathing and inelasticity permits of plugging of small bronchi. Shallow breathing fails to distend the sticky walled alveoli. Thus the near absence of inrush and egress of air results in a feebleness or absence of auscultatory sounds. Chronic pleuritis also is a factor to be reckoned with. It is always present in some degree. Its adhesions and thickenings contribute further toward obscuring the positive pulmonary signs. This explains why the signs in advanced tuberculosis are often far more in evidence in the *x*-ray than upon physical examination. I think the faintness of the physical signs is in itself a prominent and noteworthy feature in the diagnosis of pulmonary tuberculosis.

The autopsy report follows. Note how closely the *x*-ray film pictures these findings.

"Lungs: The left shows a large cavity at the apex with a capacity of 100 c.c. and four or five smaller cavities in the lower part of the upper lobe. These all contain reddish, thin pus. There are numerous small consolidated areas, which are breaking down in the center, scattered about the lung. There are several hemorrhagic areas. The right lung, likewise, has a large cavity at the apex of about 50 c.c. capacity. There are numerous consolidated areas and cavities throughout the upper lobe. There is considerable air-containing tissue in the lower lobe. The bronchi are markedly congested and contain pus. The right pleural cavity is nearly obliterated. The left pleural cavity shows many adhesions and small areas of fibrous exudate."

THE MANAGEMENT OF TUBERCULOSIS*

Part II

H. T. Burns, M.D.
Acting Superintendent State Sanatorium
Ah-Gwah-Ching, Minnesota

THE average patient who is confronted with the diagnosis of pulmonary tuberculosis for the first time is brought to face a dilemma, of which, regardless of how he adjusts himself to the exigencies of the situation, he finds himself decorating a horn. Life has not trained him to change easily from one environmental adjustment to another. The privilege of survival has been granted to many ancestors, and finally he himself as a reward for effort and struggle. Generations of such effort and struggle have succeeded in the creation of a personality whose existence is altogether dependent upon factors that compel the individual to assert himself and to try to dominate some portion of his environment. A positive militant personality he has, and as a reward he has survival.

In the sanatorium we have attempted to provide an artificial, entirely passive, non-resistant environment, with the expectation that all personalities handicapped with the duties of presiding over the destinies of diseased bodies will adjust themselves to the environment prescribed. The difficulties encountered form the bulk of the problem in the management of tuberculosis. The cure of tuberculosis in reality becomes to a large measure a struggle between the patient and his environment. He does or eventually will feel himself physically unable to assert himself in the old environment, while towards the new one he has a strange feeling of inadequacy. The tuberculosis patient in his attempt to adjust himself does so through a series of "trials and errors," which may eventually be successful, but which in the meantime has contributed greatly to the problems underlying the management of tuberculosis.

The medical personnel can be of great assistance in aiding the patient to become a part of his new surroundings. Immediately upon entering the sanatorium the professional relationship of physician and patient must be established and carefully maintained. It does not matter whether the patient gradually passes into a domiciliary existence or rapidly becomes afebrile and convalesces towards an arrested state, the doctor must cherish and preserve that bond of confidence and respect that makes the one the physician and the other the patient.

The nursing profession nowhere contributes more to the relief of the pain and suffering of mankind than in caring for those ill with tuberculosis. To render adequate nursing service it is essential that a kindly professional bond be established and continued, the same as must exist between the patient and the doctor. The doctor and the nurse, and the social worker, must establish themselves on a professional basis with each patient as they are admitted. Break this relationship and the patient has neither doctor nor nurse; he is left alone in a scientific institution with the responsibility of the cure in his own hands. With a personality developed and trained for survival through struggle he often becomes his own worst enemy. The sanatorium can provide the best environment for the cure, but without the proper professional attitude of the staff towards the patient the sanatorium may in reality become a dangerous place for the patient to seek out as a haven to aid him towards convalescence.

With the development and maintenance of an efficient medical staff it is essential to have heads of departments who understand their own duties and the relationship they have towards the organization as a whole. The superintendent of the sanatorium must surround himself with loyal and intelligent lieutenants. Heads of departments must be capable of conducting their work with all other departments in the institution. Such a staff must not only be willing but they must show an interest and a desire to lend themselves to the labor and team work so essential to successful administration. In order that a staff may be held together, the various departments coordinated, it is essential that their duties and responsibilities be carefully defined. There are few methods more helpful to the employe in orienting himself and his duties than by the aid of diagrammatic charts.

At times the chart may require some revision,

*Concluded from last month.

but this does not occur often and serves as a guide that becomes helpful to each department. Most administrative difficulties arise where duties are not or cannot be so readily visualized.

The patient who becomes employed frequently presents difficulties to the administration; this is especially true if employment is given in the same institution where the cure was taken. He frequently has difficulty in separating himself from the cure—so much so that his value as an employe is greatly diminished. Time and application often are sacrificed because of habit, and essential work becomes neglected. Another difficulty encountered by the patient employe is in his giving loyal support to the administration and the policies of the institution. While on the cure he may not have broken rules himself and he may not have interfered in any way with the successful application of the principles of the cure, yet he belonged to a specific group, a fraternity of human beings for whom the policies were made to guide and regulations to protect. It is usually considered poor sportsmanship for patients to report on one another, for one to interfere in any way with the activities of others in his group. After months of association with other patients it becomes very difficult for the patient-employe to aid the administration when both experience and training have taught him to remain passive and quiet. Once a patient, it is very difficult for some to ever cease being one, especially so far as their contact with patients in the sanatorium is concerned. It is, however, essential that the patient-employe adjust himself to the new rôle of employe and that he forget his old rôle of patient if he is to make himself of any value to the institution which once cared for him and now pays him. The patient-employe has a difficult and important adjustment to make which he usually makes unaided and unadvised, and if he fails his employment is terminated. The incident becomes an unhappy memory, his first attempt towards rehabilitation.

The employes constitute a definite corps of individuals employed for a special purpose, which cannot be realized if associations with patients are permitted. Since employes cannot associate with patients in the interest of good treatment and good administration, patients must be allowed certain privileges amongst themselves. Associations and friendships so formed should not be given too much encouragement, since great harm may be done some patient and the purpose of the institution altogether misunderstood.

The patient must be encouraged to feel that he is an important part of the institutional program. In fact, the organization is built about his requirements of care and treatment. A chart such as we use at Ah-Gwah-Ching is of great aid in arousing the patient's interest as well as in aiding him to orient himself on the road to a cure.

Tuberculosis patients who are non-toxic and afebrile over long periods of time, but who nevertheless have considerable infiltration with positive sputum, and possibly other signs, frequently wish to break the monotony of the cure by visits away from the institution. There are few experiences more detrimental to good treatment than such visits. Such visits are often called vacations, and "vacations from the cure" they surely are. Months of time and public money are wasted within a very short time, and frequently the patient returns with extensive spreads, serious complications, to remain a bedridden case for weeks as a result of his journey.

The institutional management of tuberculosis finally resolves itself into the preparation of the patient for discharge and return to home and employment. This is the most important event that has occurred since the period of breakdown. Just how is he going to adjust himself to his new problem and who is there to aid him after leaving the sanatorium. While on the cure and convalescing in the sanatorium, has his physician prepared him for this day? Just how far will his family and associates coöperate in his readjustment to a post-sanatorium life, free of long hours, excess and strain? How well does he understand that it is not usually the job that reactivates the reclaimed tuberculous but the excesses and excitement of the social and home life that begin and end the day? How well has the sanatorium instructed the departing patient to a realization of his future physical limitations and how well has it trained him to confine his activities within such limits? One of our chief functions in the management of the tuberculous is to appraise the patient's capacity for training and to teach him the problems of rehabilitation, a problem which eventually will be his to solve. The sanatorium must be an instruction center in tuberculosis; it must advise and guide each patient separately for each has his own personal.

social, family and industrial problems to meet. Without assistance he will become beset with many difficulties and dangers. Dr. Hawes has well said:

"Those of us who are interested in stamping out tuberculosis are gradually coming to realize that no system of sanatoria, no matter how complete and elaborate as to location, number of beds, surroundings, etc., can by itself solve the tuberculosis problem. We have come to realize that the patient's stay at the sanatorium or hospital, short or long as the case may be, is but an incident in a course of treatment, the most important parts of which are before the patient enters and particularly after the patient has left the sanatorium."

"The whole question of the results of our sanatorium treatment is so intimately bound with the treatment of the patient after leaving the sanatorium—after-care work—that it is difficult, if not impossible, to tell which factor is most important, treatment in the sanatorium, or the treatment of the patient after he leaves the sanatorium."

One of the most interesting phases of the management of tuberculosis is the reaction of the patient towards the modern interpretation of the cure. Tuberculosis control and treatment is warfare in every sense of the word. Defensive warfare has never won a campaign. The modern anti-tuberculosis worker has adopted a program of aggression and offense. As long as contact and pressure is applied all along the line, positive and continuous results may be expected in favor of the aggressor. The patient entering the sanatorium was at one time expected to place himself upon a cure extending over a long period of time requiring infinite patience, without assurance or promise of end-results. Accidents and tragedies incidental to the cure could be easily ascribed to his errors of omission or commission. The patient entering the sanatorium left his hope behind or placed it in storage for possible use at some uncertain future date. Upon entering the routine of the cure, he frequently felt that a bell had been placed upon his neck, and in this mental attitude spent his rest hours and others, philosophizing over the futility of his objectives—the convalescence of a diseased body followed by the readjustment of a handicapped personality. As a result of this long, indefinite, defensive attitude, getting little else than good fellowship, could the patient do otherwise than seek essential outlets for his pent-up emotions? The sanatorium in the past has been a school of incorrigibility for many patients who, under ordinary conditions of life, would be both normal and stable so far as the emotions are concerned. The sanatorium has often failed to reach into the patient's personality and make itself his guiding star over the rocky and uncharted road leading to a maximum convalescence, and the possibilities for an approximate social and industrial readjustment. The sanatorium no longer pursues a passive policy in the care of its patients. It now offers a positive program, and in so doing it has changed a waiting, defensive battle into one of offense.

The patient is now taken into an active partnership in this organization whose chief business is the sale of the cure. He no longer is expected to accept a program of indefinite waiting for a cure to overtake him, a cure constantly chaperoned by the fear of catastrophe. Together the patient and the sanatorium make a positive and united attack upon the disease. The institution is a partner with each patient, and they work out their plans of attack together. The management of tuberculosis has, within a few years, changed from the formality of record keeping and the housing of patients, to a scientific medical service for the community who have been or will become infected or clinically ill with pulmonary tuberculosis.

COÖPERATION OF THE DENTIST WITH THE SURGEON IN A GENERAL PHYSICAL EXAMINATION*

W. W. Larson, D.D.S.
Starbuck, Minnesota

DURING the last decade or two, medical and dental research and practice have demonstrated conclusively that the two professions have certain interests in common. This change to a very great extent has been brought about through the appreciation of the importance of focal infection. Definite proof exists that infection of the teeth and tissues of the oral cavity contribute largely to disturbances in other parts of the body. This fact at the outset infers that the physician must broaden his field so as to include the mouth in his search for possible points of infection.

Dentistry, therefore, should be regarded as a special branch of medicine and the dentist as a specialist should be called in consultation routinely as is the roentgologist, bacteriologist, urologist, pathologist and ophthalmologist. Present day medicine tends toward closer coöperation with the dentist.

Since Billings, Rosenow, and their co-workers called attention to the oral conditions as causative factors in disease, these conditions have assumed great importance in medicine. Up to this comparatively recent date there was little knowledge in the medical profession of the part diseases of the mouth and the teeth play in the general health of the body. It was assumed that the teeth were devoid of the capacity of self repair, that dental disorders could be remedied by mechanical means alone, that all teeth, whether healthy or diseased, could be broken off or extracted without serious effect on the welfare of the body as a whole. As a result of these assumptions the profession of medicine gave little attention to the health of the teeth. But the theory of focal infection has greatly changed this condition. It has been determined through research and observation that original foci of infection are usually found in certain tissues or organs, such as the prostate, uterus, rectum, sinuses, appendix, gallbladder, teeth and tonsils, and of these undoubtedly the teeth and tonsils rank as the greatest offenders.

Now, it is not the intention of this paper to go into the subject of focal infection. I think it can quite generally be conceded that if infection in some part of the body is causing disease in some other part, the removal of the former will often result in the restoration of health. What would perhaps be of some interest would be some suggestions as to how the two professions can coöperate, what conditions in the mouth point to the possible hidden infection, and what should the M.D. expect of the dentist when he refers a patient to him for complete oral examination.

A physician, if he were to make a general inspection of the mouth, could with a good light and mouth mirror often detect conditions which he might suspect of hiding infection, such as gold crowns, which often cover dead teeth. This is the result of a belief in the dental profession some years ago that if a tooth was to be crowned the nerve should be taken out first. Peg teeth, or porcelain crowns on posts extending into the root canals (fortunately not used so much in this day) are of course always built on devitalized teeth. Dark teeth are usually dead although some years ago a silver cement was in common use for setting inlays and bridges which in time resulted in discoloration. Silver fillings also have a tendency to darken teeth. Fistulas or gum-boils always indicate infection. Pyorrhea, although apparently offensive, can often be rendered practically harmless as a source of infection with proper treatment and home care. The above conditions can be observed in a general examination. But if thorough report is desired, we must go more into detail, and for this the case should be referred to the dentist.

An oral examination by a dentist should include: (1) a survey of the soft tissues for lesions such as cancer, mucous patches, etc.; (2) examination of the gums for pyorrhea, Vincent's angina, etc.; (3) *x*-ray examination of all the teeth, preferably of fourteen films, and extra-oral plates if necessary. Many times we find swelling or edema in the region of the low third molar where only plates made extra-orally can be employed successfully. The *x*-ray

*Read at a joint meeting of District Dental Society and the West Central Medical Society at Morris, Minnesota, October 9, 1929.

will many times disclose conditions which we would not think of allowing to remain if we knew of their presence. A full-mouth *x*-ray examination has for some years been part of the routine physical examination at the Mayo Clinic. This is limited not only to patients that have teeth but also to edentulous cases. Even in the latter class records show that 31% have infected areas. Thermal and vitality tests are important because a tooth may be dead and still the *x*-ray not reveal such an existing condition. If there is no response to the vitality test there is no question but that the tooth is dead. Three years ago a man of forty-five was referred to me for oral examination. His symptoms were nervousness, restlessness, a very tired feeling and insomnia. Two abcessed teeth were found. These were extracted with resultant rapid recovery. Two months ago this man came in and asked to be examined, saying that he was suffering from the same symptoms that he had three years previously. The *x*-ray revealed no pathologic process but the vitality test disclosed one tooth that gave no response. In view of past experience in this case, it was decided to extract it and within two weeks he was back to normal. Transillumination often reveals pathologic conditions of the soft tissue that are not registered by the *x*-ray. Looseness of the teeth, discoloration, and pain deserve notice.

Although a written report on the results of the findings may be desired by the physician, perhaps the most satisfactory method would be to go over the findings together. It would perhaps be advisable not to decide on extraction of teeth until infections from other sources are first eliminated and then ask the question, is this tooth doing more harm than good systemically, as part of the organ of mastication, bearing in mind the lack of proper preparation of the food in the mouth may also have a vital effect on health.

Within the ranks of the dental profession there is a considerable difference of opinion as to when to extract pulpless teeth. Dr. Sterling V. Mead of Washington, D. C., who has devoted many years of study to oral pathology and its effect on health, says: "With very few exceptions I think the following teeth should be removed—1. All teeth showing periapical bone involvement. 2. All pulpless teeth in patients whose health is seriously endangered. 3. All pulpless teeth showing marked periodontal bone resorption. 4. All pulpless teeth bordering directly on the maxillary sinuses. 5. All third molars when pulpless or causing pressure or decay in other teeth. 6. All pulpless teeth whose root formation precludes the possibility of a good root canal filling. 7. All pulpless deciduous teeth."

In regard to pulpless teeth Dr. Gardner of the Mayo Clinic says: "Extensive bacteriologic investigations at the Mayo Clinic and elsewhere have demonstrated that even pulpless teeth which show little or no evidence of infection from the roentgenologic standpoint are usually infected. The percentage is so high that all pulpless teeth must be considered potential foci of infection and should be extracted if the condition of the patient requires the elimination of all dental infection."

Now, I do not know how many dentists and physicians in this audience are working together on physical examinations but I feel that to many of us it is somewhat of a new field. Just how successfully this work will be carried on will depend to a large extent on how we as dentists measure up when the physician refers cases to us. In making our examinations we must be thorough and in our report we must state our findings and recommendations in a definite and scientific manner, thereby becoming of such valuable assistance to him that he will feel that no diagnosis is complete without our report on the conditions of the mouth. Create in the physician a wholesome feeling of confidence in our ability as disgnosticians of the oral cavity. To do this we must have the data at our fingertips and know what we are talking about and, most important, have the courage of our convictions. I think we may rest assured that the physician will be delighted to meet us more than half way and will place his confidence in the same proportion as we have demonstrated our ability. He is only too glad to leave the dental field to the dentist, but he wants to be sure to leave it in the right hands. It is admittedly a difficult program to work out and will require tact together with constant study, ingenuity and the proper spirit. But when this coöperation is attained, we will have a feeling that dentistry has been lifted another step upward and that we rank in our profession on a par with the older profession of medicine.

THE RECOGNITION OF GLAUCOMA BY THE GENERAL PROFESSION*

WALTER H. FINK, M.D., M.S., F.A.C.S.
Minneapolis

The purpose of this paper is to call your attention to the importance of the early recognition of glaucoma. When we realize that six out of every one hundred new eye cases entering an oculist's office are those of glaucoma,[23] and that glaucoma causes one-fourth to one-third of blindness past middle age,[8] we are impressed with the importance of the condition. It is, therefore, reasonable to expect that each of us, no matter what branch of medicine he is practising, will at some time come in contact with glaucoma. Whether or not it is recognized depends upon our knowledge of it and especially our knowledge of the earliest signs.

My object is, therefore, to emphasize two important factors: first, the importance of recognizing glaucoma early; and, second, the early manifestations of glaucoma.

The early recognition of glaucoma is of paramount importance because at this stage our treatment is most effective and little damage has been done to the eye, whereas, if treated when the disease is fully established, irreparable damage has been done to the eye and the operation which must be resorted to is ineffective in checking its progress. This statement is evidenced by the variety of treatments both operative and medical which are being utilized today. It is an established fact that in an eye which is glaucomatous the visual acuity is progressively lessened and will eventually end in blindness if not treated. It is also a fact that vision which is lost is never regained in spite of all our treatment. Expressions by the following authorities substantiate these statements: Fuchs,[55] one of the greatest authorities, states, "Its accurate recognition is of the greatest importance to the practitioner, the more so because here prompt and proper therapeutic interference can save everything, but a false diagnosis and improper treatment may destroy everything. Unfortunately, we still constantly get under observation many cases of glaucoma which have been incorrectly diagnosticated, and which come to the ophthalmologist only when help is no longer possible." Thomasson[16] states, "To defer a diagnosis in a case of glaucoma until obvious structural changes are present would be as inexcusable as it would be in the case of pulmonary T.B.C. to wait for obvious cavity formation and for the appearance of the tubercle bacilli in the sputum before making a diagnosis. Each disease must be diagnosed in its incipient stage if we wish to prevent irreparable damage and thus render to our patients the service they have a right to expect from us."

Hence, we see that the longer the diagnosis is delayed the more vision is permanently lost and the less our chance of checking the progress of the disease.

Glaucoma is the problem of the entire profession. In everyday practice the oculist is frequently confronted with the question—Why is it that we do not see the cases early instead of in a well advanced stage, and very frequently when the eye is totally blind? He is put in the same position as the general surgeon who is asked to cure an extremist or after the patient has expired, as a dead eye from the visual standpoint to the oculist is the same as a dead patient is to the general surgeon. In order to correct this situation so that the cases will be seen earlier we must realize the fact that recognition of glaucoma is not alone the oculist's problem but the responsibility of the entire profession, especially the general practitioner. It is he who is in a position to make the early diagnosis as the patient usually comes to him because of indefinite symptoms either directly or remotely related to the eye. He should regard every person over 40 who comes to consult him because of indefinite complaints as a possible glaucoma case until the contrary is proved. Experience has shown us that if glaucoma be constantly borne in mind a considerable number of cases may be picked up which would otherwise go unrecognized until a late stage of the disease.[10] One is often told by medical men that they have never seen a case of glaucoma and that it is so rare that they are justified in ignor-

*Presented before the Asbury Hospital Staff, Minneapolis, February, 1929.

ing it. This is a fallacy, for at least one patient with glaucoma presents himself to the general practitioner every few years.

It is not necessary that the physician be highly trained in ocular diagnosis to recognize glaucoma. There are some cases extremely difficult to diagnose but in most instances there is evidence enough to cause him to suspect its presence. The following statement by Wilder[7] is significant: "Ignorance in regard to this dreaded condition should not exist. General physicians should be impressed with the importance of the early recognition of it, and although they may do no ophthalmic work should be able to recognize it, or at least in more insidious cases to suspect it. Errors of recognition are not necessarily due to ignorance, but may result from oversight because of multifarious duties the general practitioner must assume." As stated by Derby,[8] "Glaucoma is the one important cause of loss of vision in which no concerted effort at conservation has been made. The physician who passes his eye cases over with a hasty inspection, or who allows himself to be beguiled into the practice of prescribing eye washes for all eye disorder, will, sooner or later, make some error fatal to vision which might have been avoided."

It is only through the coöperation with other branches of the profession that the oculist can hope to obtain glaucoma in the incipient stage.

The second point I wish to emphasize is that the early signs of glaucoma are definite. If this is so, why is it glaucoma is not recognized early? This, in my opinion, is due to the fact we are not entirely familiar with its early manifestations, and consequently the condition is overlooked. Most of our schools in teaching this subject dwell at length upon the fully developed and advanced stages of the disease and as a result our conception of the symptoms of glaucoma are those of the well established glaucoma. Very little is said about the early signs and therefore we think of the condition only when it has passed into the well established period. It is very evident that if we are to make any progress in the prevention of glaucoma it must be made along the lines of early recognition. This thought is well expressed by Batten,[2] who says, "Our knowledge of the premonitory symptoms of glaucoma is very limited, and has not received the attention the subject deserves."

In order to obtain a clearer picture of the earliest manifestations of glaucoma, I wish to present the following cases. Each case has a characteristic onset and illustrates some of the ways glaucoma in its earliest stages makes its presence known. In presenting these cases certain phases have been purposely omitted for the sake of conciseness, and only the essential features relating to the onset are considered. Therefore, no attempt will be made to discuss the cases completely as the omitted features have no bearing on the present discussion.

Case 1.—

History: Miss E. G., aged 55, had been known all her life as a "high strung and nervous" person. For 12 years previous to her present illness she had been under medical care because of high blood pressure. She was easily upset and tired very readily. Glasses had been worn constantly for years for a high hyperopic error. Last refraction was done six years previously. Recently, because of financial reverses, she had been forced to work for her living. The work necessitated the prolonged use of her eyes and expenditure of much nervous energy. She returned home at night exhausted. One evening after a strenuous day she noticed a dull ache in the right eye. This became progressively more pronounced and she was forced to call for relief. Ophthalmoscopic examination showed well advanced atrophy and cupping of the nerves of both eyes. On questioning, it was determined that her mother had glaucoma. A diagnosis of acute congestive glaucoma was made.

This case presents a number of features which should make us at once suspicious of a glaucomatous tendency and should focus our attention on the eyes. All treatment and attention had been given to her general medical condition and the eye disregarded. The result was a hopeless case of well advanced glaucoma. The features which are significant are:

Age: In this case the age was 55, which is the age at which glaucoma is most frequently seen. It is a common observation that most cases of glaucoma occur in middle and late life, and statistics confirm this. "It is not an unwise policy to be suspicious of every eye patient 40 years of age or older, until by careful study we can declare such a patient free from glaucoma." (Peter[23]).

Sex: In this case the patient was a female. Although many cases are seen in males, most authorities agree that it is more commonly found in females.

Inherited tendency: If a family history of glaucoma is present we should be on our guard as there is a decided familial tendency. Familial

glaucoma, according to Lamford, is continuous in descent and is transmitted by both sexes.

Refractive error: The patient was highly hyperopic. It is generally accepted that to patients who have a high degree of hyperopia, we are justified in recommending periodic observation, and to report the appearance of any suspicious symptoms of glaucoma. In general it should always be borne in mind that hyperopes with small short eyes are chiefly the subjects of such tendency.

Vascular changes: The patient exhibited a hypertension. Arteriosclerosis is frequently present and the blood pressure is usually elevated. The study of clinical material teaches that the individual suffering from glaucoma in 90% of the cases is not alone suffering from his eyes, since he is also suffering from a general vascular affection. Charlin had studied the cardiovascular condition in 100 patients suffering from primary glaucoma, of whom 90 presented evidence of vascular disease.

Nervous instability: Glaucoma occurs mostly in people who are of a more or less neurotic temperament and who are under a great mental strain. It is commonly observed that grief, anxiety, and worry act as exciting causes of attacks of glaucoma. Hamberger considers glaucoma essentially an expression of some such irritating influence from the central nervous system. Bilger regards it purely as a vaso-neurosis, comparable with migraine.

General medical condition: There is no disease of the eye in which it is more important to take a careful account of the general physical condition and health of the patient than in glaucoma. Probably the more we learn about ocular disease the more widely will we perceive its relation to the general condition. La Grange in his latest book says that glaucoma is generally not a local disease but an ocular condition occurring in an already diseased organism. Glaucoma rarely occurs in individuals in good general health.

Case 2.—

History: Mrs. H. A. G., aged 60, had noticed for the past two years that her eyes tired very easily and because of this early fatigue she had consulted her oculist several times. Each time the reading glass was strengthened and for a time following each change was relieved. As the relief was not permanent she decided to try another doctor.

Examination revealed nothing suggestive in the external examination and the vision was normal. Perimetric study showed a marked contraction of the visual fields, leaving only the central vision intact. Ophthalmoscopic examination showed a typical glaucomatous cup in both nerves. Other tests substantiated the diagnosis of chronic noncongestive glaucoma of long standing.

This case shows how insidious the onset of glaucoma may be. The only symptom which should have aroused suspicion was the ocular fatigue. It is also important to note that the central vision was normal even though the peripheral vision was gone. The measurement of central vision is of no value as a gauge of the progress of glaucoma until the disease has reached a late stage. Fuchs[55] states, "The diminution of the central vision often develops late, when the field of vision has already become very small, so that patients may carry on fine work while they are scarcely able to go about any longer. The patient often does not become aware of the existence of the disease until late." The patient's eyes tire very easily, and, thinking it is only a question of procuring stronger reading glasses, he goes to the optician and finds that he gets on much better with the new lenses, but after a time again finds increasing difficulty in reading, especially at night. This is to be regarded as a very dangerous and characteristic symptom in a person past middle age. Therefore, frequent changes of glasses, especially rapid changing of near vision or premature reading glass, should arouse our suspicion. Roemer[54] states, "Unusually rapid recession of the near point is noticed long before other signs of glaucoma become manifested." Priestly Smith states, "When patients between fifty and sixty years of age desire to change their reading glasses frequently or to use one stronger than is suited for their age there is reason to apprehend the onset of glaucoma." These patients often put the matter off indefinitely with the entirely satisfactory explanation to themselves that it is due to a little overuse of their eyes, and that a good night's sleep will straighten them out.

Case 3.—

History: H. J. L., aged 55, had noticed for the past year that his vision was foggy at times. Two months ago he noticed that he could not see so well with the left eye. Since this time it has progressed and recently he has noticed that the vision in the right eye was less. Being alarmed, he consulted his doctor and was told that the condition was cataract but was too early for operation. He was advised to return in six months for a check up. Being dissatisfied with this advice he decided to get an oculist's opinion.

Examination: Externally the eye was normal. Ophthalmoscopic examination showed no evidence of cataract but a definite early cupping of the disc was seen. A moderate degree of ocular hypertension was present. The diagnosis of chronic noncongestive glaucoma was made.

This case is another example of how chronic simple glaucoma is manifested. Visual failure may be the only symptom and is frequently observed for a long period before the other signs of glaucoma become manifest. Dimness of vision or foggy vision may also be noted. In describing their symptoms some patients speak of cloudiness of vision, some of seeing through a smoke, while others state that there is a fog in the atmosphere. Some patients complain that these mists are very bad in the early morning and gradually pass away as the day goes on. Others have them later in the day and attacks synchronized with periods of fatigue; but food, rest, or diversion relieve them. Very frequently this reduction in vision suggests cataract formation to the physician, and experience shows that patients have been advised that cataracts are forming and to report at a later date to the oculist for operation. This grave error can be easily avoided by the use of the ophthalmoscope which shows the lens to be clear. The following statement by de Schweinitz[56] is significant: "It is an inexcusable error to confound the failing vision of chronic glaucoma with cataract. Eyes have been permitted to pass into blindness and their possessors deluded with the hope that they are waiting for the ripening of a cataract." The history of gradual painless loss of vision combined with the increased density of the lens in old age, giving a slightly yellowish reflex when light is thrown in the pupil, quite naturally suggests the condition of cataract. Chronic simple glaucoma is not simple to diagnose. The tension is often not much increased, requiring a tonometer to detect the increase. The pupil is often normal in size, there is no congestion and, most misleading of all to the man who thinks of glaucoma only as acute glaucoma, there is no pain. The history is usually exactly like that of cataract—a gradual decrease in vision usually affecting one eye first and then the other. If no opacity is seen, it is practically certain that some other condition than cataract is present, and this is quite likely to be chronic simple glaucoma which requires very prompt and careful treatment if any of the little sight that remains is to be saved.

Case 4.—

History: H. L. P., aged 45, had noticed for the past six months that his eyes have been slightly inflamed, more pronounced at times. Whenever the eyes were more inflamed there was a slight dull pain in the region of the eyes. His vision had not changed. It was impossible for him to use his eyes for close work because of the early fatigue and discomfort which followed. Ordinary daylight would cause discomfort. During the attacks of more pronounced congestion he could see rainbow rings around electric lights or had a misty vision. This would pass off in a short time.

Examination: The deep vessels of the globe surrounding the cornea were larger than normal. The anterior chamber was shallow and the pupils partially dilated. Their reactions were sluggish. Ophthalmoscopic examination showed a normal colored nerve head with a deep cup which did not extend to the edge of the disc and no bending of the vessels as seen in glaucoma. A venous pulsation was visible at the edge of the cup. Tension was normal at the time of the examination, but when followed for a period of several days, showed a typical glaucoma curve. Adrenalin was instilled and caused the tension to increase slightly. Perimetry studies showed a slight enlargement of the blind spot towards the macula. A diagnosis of subacute congestive glaucoma was made.

There are several features of the case which are characteristic of early glaucoma. Halos or rainbow rings around lights is a very suggestive sympton. They are usually associated with foggy vision. Mists and halos are often the earliest evidence of the disease which attracts the patient's attention and are a very delicate symptom of a rise in intra-ocular pressure. In the early stages of the disease, these phenomena are transient and rapidly come and go; but later on they assume a more permanent character. It is not uncommon to meet with glaucoma patients whose complaint is that from time to time they have seen colored rings around lights, and in whom no other evidence of glaucoma can be elicited by even the most careful examination. Most frequently we get a history of the rings appearing for short periods, when the patient is tired, and passing away when he gets a meal and rest.

Another important feature of this case was the shallow anterior chamber. This condition when present should put us on our guard. It may be a physiological condition, but it is generally admitted that when the anterior chamber is shallow an investigation is called for, especially if associated with a congested eye. Shallowing of the

anterior chamber is the most constant of the signs of glaucoma visible on simple inspection. It is due in most instances to the forward displacement of the lens. A fairly deep anterior chamber does not preclude the existence of glaucoma. A shallow chamber, on the other hand, furnishes a suspicious link in the chain of evidence which may be gathered when symptoms are carefully analyzed.

Pupillary changes likewise are important to note. A shallow chamber with a small tight pupil is the usual finding in middle aged people. But when such shallow chamber is associated with a pupil of 4 mm. or larger that reacts but little to light or accommodation in people of that age, it should immediately arrest our attention. It is important to note that in eyes suffering from, or predisposed to, glaucoma the instillation of a drop of eserine lowers the intraocular tension, while a drop of homatropine raises it. This does not occur in normal eyes and is a fact of some use in cases of doubtful diagnosis. Also, in the normal eye the instillation of adrenalin has no effect on the pupil, but there is no doubt that the Knapp adrenalin mydriasis test is positive in a very large majority of glaucoma patients. While discussing pupillary changes, it may be of interest to mention a recent observation made by Koeppe. He has claimed that glaucoma can be recognized even in what he terms the "preglaucomatous stage," by the aid of the Gullstrand slit lamp, months or a vear before any other sign of the disease has appeared. He states that as a result of the morbid changes, which are taking place, pigment granules are set free; and that these wander out in the form of a fine dust, and are to be seen on the surface of the iris stroma. The observation has been both supported and contradicted. Another recent observation which is closely associated with the above discussion is the work of Uribe Troncoso. He has devised an instrument, the gonioscope, for examination of the angle of the anterior chamber. A disposition to glaucoma is often indicated from the angle of the anterior chamber and the presence of synechia. Often in early glaucoma one can find brown or black pigment spots of pigment epithelium origin in the region of Schlemm's canal.

Perimetric examination of the above case showed a characteristic finding of early glaucoma, namely, enlargement of the blind spot towards the macula. Examination of the visual field, when suitably conducted, furnishes the most delicate and the most reliable indication of the early pressure of incipient glaucoma. The earliest changes appear within an area of 26 degrees of the center of vision. They are best determined by working at a distance of one meter on a special perimeter called the scotometer. According to Thomasson[16] this test is "probably the most important aid to the diagnosis of glaucoma at our command. It enables us to discover an almost infallible sign of this disease long before any subjective symptoms are constantly present." Elliot also considered it the most important procedure of all. By this method certain changes are mapped out which, although not absolutely pathognomonic, are considered very reliable evidence of the presence of glaucoma.

The optic nerve change in the above case brings up a very important point. The disc was normal in color and had a physiological cup. Beginning glaucoma may be present with a disc which has a so-called physiological cup. The physiological cup is described as a partial cupping not deeper than the lamina cribrosa, and not extending to the disc margin; also, the vessels do not emerge sharply at the margin of the disc. We must not feel that a disc having a physiological cup is free from glaucoma. Experience has shown us that a deep physiological cup may later progress into a true glaucoma cup. It is well to regard large excavated cups, especially those approaching very nearly to the temporal margin of the disc, with suspicion.

There are other changes in the disc which appear early, and are considered by good authorities to be significant, and which can be depended upon as an indication of incipient glaucoma. When a depression of the disc, however shallow, shows abruptly at the disc margin and the vessels bend sharply as they cross the margin, we have a definite sign. It is also suggested when the disc surface shows a decided slope from the cup margin to the disc margin. Hyperemia of the optic nerve or edema of the nerve head may precede the cupping. Pallor of the disc is seen occasionally very early. The optic nerve changes as an aid to early diagnosis of glaucoma, so far as the characteristic cupping is concerned, are not of much value, because by that time the disease has become firmly es-

tablished and has existed for some time. We must recognize the condition while the nerve head is a healthy pink and before atrophy has taken place. Recognition of the disease at this stage is of vital importance.

A venous or arterial pulsation at the edge of the disc should arouse our suspicion. In most normal eyes a slight venous pulse can be distinguished, and if the pressure within the eye rises, one of the first results is an accentuation of this venous pulse. If a further rise in pressure takes place, pulsation is communicated to the arteries as well as to the viens, and may become a very marked feature of the ophthalmoscopic picture.

The measurement of intra-ocular tension as an aid to the early diagnosis of glaucoma is of value especially when the other symptoms are doubtful. Hypertension of low degree can exist for a long time without other symptoms. It is therefore important that this be looked for in making an early diagnosis. Measurements obtained by the use of the tonometer will show slight variation from the normal. The old method of finger tonometry is only of value as a preliminary test and then only when there is considerable variation either too high or too low. But for certain limits it is valueless and may be misleading. An important point to emphasize is that a single reading is of no value unless there is a marked variation from normal, but when the change is not pronounced or normal, a series of measurements is necessary and should be recorded like a temperature chart. It is important to know that the tension should not differ materially between the two eyes and a tension which is normal in one man's eye may be pathological in the eye of another. A low tension may be measured in an eye but may be pathological for it, and so also a slightly higher than normal tension may be normal for another eye. The tension may be within normal limits in many cases of definite glaucoma. If this is so, how are we to determine when the tension is pathological? This is determined by the daily pressure curve which is typical of glaucoma. There is evidence to show that the normal eye varies but little during the day, whereas the glaucoma there is a typical variation. It is maximum in morning and minimum in the afternoon. According to Hagen[33] the pressure curve is a means by which diagnosis is made earlier than by any other method. The whole curve may be below normal tension or normal all the time, yet the pressure curve show glaucoma present.

Variation in tension on dark adaptation is important in early diagnosis. Frigenbaum has shown that in a dark room, an eye with glaucoma rises in tension over 6 mm. of mercury, whereas in the normal eye a slight change is noted over a longer period.

The effect of massage on the glaucomatous eye is of practical value in diagnosis. It has been observed that massage which would lower the tension of a normal eye appreciably has comparatively little effect upon a glaucomatous eye. According to Thebert this reaction is important in early diagnosis.

It may be of interest to mention a test which, although in the experimental stages, will eventually prove to be of value in the early diagnosis of glaucoma. This is the alteration in light sense. There is good reason to believe that a slight failure in light sense is one of the earliest indications of the onset of glaucoma. In cases of incipient glaucoma it is believed a rise in light minimum curve is often the earliest sign. It has been demonstrated that after glaucoma has developed in one eye only, the second eye, although entirely free from glaucoma so far as usual signs and symptoms are concerned, may foretell its own development of the same disease by showing changes in the light sense, a slowing of dark adaptation, and an increase in the light minimum.

Another test which may prove to be valuable is the increased permeability of the capillaries, a diagnostic sign of glaucoma which has been suggested by Thiel. Sodium fluorescein is given the patient by mouth, and its appearance is looked for in the aqueous humor by means of the slit-lamp. In the normal eye it is not detected, but in iritis and glaucoma this writer claims that a fluorescence is visible in the pupil. Although this work is new, it suggests the possibility of a valuable procedure.

Case 5.—

History: Mrs. J. B., aged 65, stated that for the past two years she had noticed that her vision was "failing." This was more noticeable at times, and during these periods the vision was so greatly reduced that things looked foggy. On one occasion she was totally blind for a few minutes. During these attacks of reduced vision she noticed colored rings around electric bulbs. At times a dull ache was present in and about her eyes and the eyeballs were congested. Between

attacks her eyes felt almost normal except for early fatigue. She has been under a doctor's care for the past two years because of high blood pressure. The day previous to consulting me she had a severe headache which was centered around the right eye. This became progressively worse and she was confined to bed. She became nauseated and vomited. The vision rapidly diminished and in a few hours she could not see with the eye. Morphine did not relieve the pain.

Examination: The eye was greatly congested. The lids were swollen and the conjunctiva of the globe was chemotic and bluish in appearance (due to venous engorgement). The cornea was hazy and the anterior chamber obliterated. The pupil was irregularly dilated and did not respond to stimulation. A greenish reflex was present from the pupil, and a view of the fundus was impossible. The tension was stony hard, but was relieved by constricting the pupil with eserine. This caused the symptoms to rapidly subside. A later examination showed a marked cupping of the disc, typical of glaucoma. The vision was practically nil. The other eye showed a similar involvement but to a less degree. A diagnosis of acute congestive glaucoma was made.

This case brings up the question of differential diagnosis. Inflammation in an eye should be carefully examined before it is prescribed for and a differential diagnosis made. We should have in mind three important eye diseases in every inflamed eye we examine: conjunctivitis, iritis, and inflammatory glaucoma. No treatment whatever should be given unless we feel sure of our differential diagnosis, for the treatment of these three diseases is radically different. The treatment that will cure one will render the eye blind in the other. A simple differentiation is made by observing the following points.

Congestion: Conjunctivities presents large blood vessels superficially located in the covering of the eyeball itself. These vessels are smallest at the cornea and grow larger and more tortuous as they reach the fold or the cul-de-sac. In acute glaucoma the eye assumes a purplish hue on account of the venous stasis. In acute iritis there is more of a diffused pink color surrounding the limbus and extending over the globe.

Pain: In many cases of iritis the pain is just as severe and these cases are much more common than those of acute glaucoma, a relatively rare disease. However, the pain is much more acute in its character, much more rapid in its development and much more extensive in its distribution in acute congestive glaucoma. It is frequently mistaken for a severe neuralgia.

Discharge: This is usually present in a conjunctivitis and absent in iritis and glaucoma.

Age: Conjunctivitis is common at all ages. Glaucoma seldom occurs before the fortieth year, and iritis is rarely seen in childhood.

Tension: In acute glaucoma a careful palpation through the closed lids will often show a marked hardness of the affected eye as compared with the other eye. In iritis, however, where the lids were swollen and the eye is exquisitely sensitive, it is often impossible to press on it hard enough to tell whether it is hard or soft. The tension is increased in glaucoma and normal or even decreased in iritis.

Pupil: The pupil in both cases is relatively immobile, but is especially so in acute glaucoma, and in this condition is widely dilated, while in acute iritis the pupil is inactive but contracted, unless a mydriatic has been used, in which case the iris will show adhesions to the anterior capsule of the lens, giving an irregular outline to the margins of the pupils.

Anterior chamber: The iris is pushed forward in glaucoma, due to the intra-ocular pressure, producing a shallow anterior chamber; in iritis the anterior chamber is normal in depth, or if changed is deeper than normal.

Case 5 also brings up the question of ocular pain, which in this instance was severe. Aside from the visual changes in glaucoma, perhaps pain is the principal symptom that causes the patient to come to his physician for relief. The neuralgic pains of glaucoma may vary from a peculiar sense of discomfort to a severe pain of characteristic nature. Marked pain does not occur early in simple glaucoma, but slightly aching or asthenopic discomfort may be the first symptom. A simple glaucoma may run its whole course without one moment of pain in the eye. Again, the early slight attacks of subacute glaucoma may be attended only by mild feelings of discomfort or of ocular pressure. On the other hand, the acute disease is marked by great suffering. The trouble is not always referred to the eye. The patient and even his medical advisor may make the mistake of thinking that the cause of the trouble is in the teeth, the ears, or nose, since the "neuralgia" complained of appears to start from one of these organs.

The headaches, which make us suspicious of glaucoma, are headaches in people past middle age when all refractive errors have been cor-

rected; or headaches in elderly patients associated with vomiting.

CONCLUSIONS

Our greatest hope in arresting glaucoma lies in its early recognition because at this time its response to treatment is most satisfactory. Glaucoma is the problem of the entire profession and it is only through the coöperation of all branches of the profession that we can hope to obtain glaucoma at an early stage.

Glaucoma can be recognized in its earliest stage if we are on the lookout for it and are familiar with its early manifestations. The five cases presented emphasize some of these. Case No. 1 brings out the importance of predisposing factors. Case No. 2 shows how insidious the onset of glaucoma may be, there being no external changes or loss of vision. The only symptom was early ocular fatigue. It also shows how the reading vision may be perfect and the eye practically blind. Case 3 illustrates how visual failure may cause us to consider cataract formation and the eye slowly pass into blindness while waiting for the cataract to mature. Case 4 emphasizes several points of importance: the diagnostic value of halo vision, anterior chamber, pupillary, optic nerve and tension changes. It also shows the value of the perimeter as a means of diagnosis. Case 5 emphasizes the importance of distinguishing between acute conjunctivitis, iritis, and acute glaucoma.

Although certain cases require extensive equipment and much detailed study before a diagnosis of glaucoma can be made, the great percentage of cases can be diagnosed or at least suspected by much less study and without the aid of special equipment. The essential point to remember is that its early recognition means everything and that it is not a rare mysterious disease which interests only the oculist, but rather a fairly common condition which we all see and which we can all recognize if we are on the lookout and know its symptoms.

MUTATION OF STREPTOCOCCI: REPORT OF A PROBABLE CASE*

J. Arnold Bargen, M.D.
Rochester, Minnesota

Rosenow[3,4] (1913 to 1915) reported studies on the transmutation of streptococci and pneumococci. He demonstrated that hemolytic streptococci could be changed to streptococci of the viridans or mucosus varieties, and these, in turn, into pneumococci. The process also could be reversed. All this seemed dependent on the selection of suitable strains and appropriate methods of culturing, and, among the latter, gradients of oxygen tension apparently played an important part.

The transformation of some of the strains was found to be complete by every test known. This was proved by morphology, the presence of capsule, the fermentative powers, the solubility or insolubility in bile and in solution of sodium chloride, the behavior toward the respective broth cultures, the specific immunity as manifested by the production of opsonins and by agglutination with antipneumococcus and antistreptococcus serums and the pathogenic powers. Moreover, when the transformation was complete, the acquired properties became fixed, and the strains then behaved as did those obtained from the usual sources. To change the organisms again it was necessary to place them under stress or strain. The underlying conditions which called forth changes were favorable conditions for luxuriant growth and subsequent unfavorable conditions. New or latent energies which were previously not manifest were called forth and tended to persist. There was no question about working with mixed cultures because of each main variety of organism single organisms were obtained and so the changes observed were not due to so-called "mass selection" but to actual changes under the influence of changed environment. If such a condition could prevail under artificial growth it seemed feasible that it would also occur in vivo. Rosenow[2] observed apparent mutations in animals and almost exclusively in closed cavities, such as the joints, the pericardium, and in the pleural cavity in patients recovering from pneumonia caused by the pneumococcus. These mutations took place mostly when the tissues of the host were getting the upper hand and the organisms were being destroyed. He spoke of mutations in vitro as "retrogressive" and those in animals as "progressive" because, in the former, virulence, fermentative powers, and other evidences of a vigorous vegetative life were diminished; in the latter they were usually increased.

The bearing that these observations might have on organisms in distant foci of infection seems apparent. Foci of infection might be places through which bacteria not only gained entrance to the human body but also places where conditions are favorable for them to acquire the properties which give them affinities for various structures.

That these observations of Rosenow have a practical application is strongly suggested by some types of disease in which foci seem to play a part in the progress of the infection. Undoubtedly, many similar instances could be cited, but the case here reported illustrates numerous features supporting the hypothesis of mutation of streptococci. If there still remains disapproval of the term "mutation," there can be no possible objection to the term "dissociation," as used by Hadly to designate the close relationship of various streptococci and the probable ability of them to change from one to the other as they pass through various phases of perhaps a life cycle.

REPORT OF CASE

A married woman, aged twenty-five years, came to the clinic, September 10, 1928, with a history of intermittent bloody dysentery of five years' duration. The first attack had begun about five years before with frequent movements of the bowel, between ten and twelve in twenty-four hours at the maximum. The attack had subsided in a month. After a remission of several months, the trouble had recurred. The second time it had been more severe and the number of stools had averaged ten to twenty-five in each twenty-four hours and had contained much blood, mucus and pus.

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the Central Society for Clinical Research, Chicago, Illinois, November 22, 1929.

This attack had lasted through the summer and until fall, when her condition had become somewhat improved under local irrigations and limitation of diet. Since then there had been improvement each winter and an exacerbation each summer. The patient never had been entirely free from symptoms since the first attack. The last attack had begun about six months before she came to the clinic and had become progressively worse until her admission. In the course of this time she had lost about 30 pounds in weight.

Fig. 1. Colon after barium enema of patient with extensive subacute ulcerative colitis.

On admission the patient's weight was 82.5 pounds. Her blood pressures were 115 systolic and 70 diastolic, her pulse rate was 94 beats for each minute and her temperature 98.4° F. Her tongue was thickly coated. She seemed fairly well nourished but was of rather slight stature. There was generalized abdominal soreness, seemingly more marked along the line of the colon. The anal sphincter was very spastic and the rectum imparted a granular feeling to the finger. At no time during her stay in the hospital was anemia very marked; the lowest estimate of hemoglobin was 65 per cent by the Dare method and the erythrocyte count was 3,310,000 for each cubic millimeter. There was persistent, mild leukocytosis, ranging between 8,800 and 14,100 cells for each cubic millimeter. Urinalysis gave essentially negative results. The Wassermann reaction of the blood was negative. Early in the disease there was a report of someone having found amebæ, but at this time repeated examinations of stool failed to reveal parasites, ova or acid-fast bacilli. The roentgenogram of the thorax gave negative results. The roentgenologic examination of the colon showed evidence of chronic ulcerative colitis of the entire colon with deep ulceration (Fig. 1). Proctoscopic examination was done, September 11. The mucosa of the rectum and sigmoid was glazed and bled with slight trauma. There was extensive secondary ulceration; the lumen was contracted to about half its usual diameter. Activity of the disease was graded 2, and the diagnosis was chronic ulcerative colitis. The diplostreptococcus so commonly found in these cases was isolated from the ulcers in the rectum. Other laboratory data were of no diagnostic importance at this time.

Fig. 2. Streptococci in long chains isolated by blood culture.

Treatment with specific immune serum was begun. At this time the patient was having between twelve and fifteen rectal discharges, mixed with blood and pus, every twenty-four hours. Improvement was striking until September 25, when she had a general feeling of malaise, a slight chill and an elevation of temperature to a maximum of 103.5° F. The maximal temperature prior to this, in the two weeks she had been in the hospital, had been 101° F. There was marked tenderness over the descending colon and sigmoid, and the question of perforation was considered. Palliative measures were applied and within forty-eight hours the condition subsided. Improvement again continued until October 10, when an acute, periapical dental abscess developed, and, coincident with this, occurred the first symptoms of arthritis. The arthritis progressed rapidly, and in four days many of the joints, including the fingers, ankles, knees and elbows, were acutely tender and swollen. In the lower jaw was a typical "gum boil," which was tender and sore. By October 23 this had subsided sufficiently to allow of removal of

the offending tooth, and following its removal the arthritis subsided promptly. During the weeks of the arthritic difficulty, the colitis remained at a standstill. Large doses of the salicylates were employed in the treatment of the arthritis.

October 25, numerous red, elevated, tender nodules appeared in the subcutaneous tissues of the lower extremities, and two on the right arm. Associated with this occurred a rise in temperature to 102.5° F. In consultation with a dermatologist, a diagnosis of erythema nodosum was made. With the subsidence of the arthritis, the nodules subsided, and also the colitis, so that, by October 31, the patient was having two formed stools daily. At this time, and on several previous examinations, cardiac involvement had not been noted.

December 4, tonsillectomy was performed, and in the tonsillar abscesses discrete diplococci and short chains of diplococci were found and were injected intravenously into rabbits. Acute polyarthritis and acute ulcerative colitis developed in the rabbits. The discrete diplococcus found in the tonsillar abscesses corresponded in appearance to that of the organism which had been obtained from the rectal lesions, as it appeared when freshly isolated. The patient made a fairly uneventful postoperative convalescence, but within seven days after tonsillectomy an acute exacerbation of the polyarthritis occurred, with tender, swollen joints; however, there was only a slight exacerbation of the colitis in the form of an increase in the number of stools to four and five in twenty-four hours. The stools were streaked slightly with blood. Under heavy doses of salicylates the swelling in the joints subsided somewhat and the administration of specific ulcerative colitis serum was again begun.

December 14, after several days during which the patient had not felt particularly well, there was a rise in temperature to 102° F. At this time, on blood culture, an indifferent type of streptococcus, in short chains, was obtained (Fig. 2). When these organisms were injected into rabbits, lesions developed in the joints. This general upset lasted only three days, following which came two weeks of marked improvement, until January 3, when a sudden chill, and a temperature of 105.5° F. developed. Blood culture at this time resulted in growth of a diplostreptococcus, morphologically much larger than the first organism obtained on blood culture and resembling more the organisms of chronic ulcerative colitis. Intravenous injection of this organism into rabbits again was followed by lesions of the joints, but also by hemorrhages into the mucous membrane of the colon. Treatment with specific serum was continued, and improvement was progressive, so that by February 1 the patient was dismissed from observation. She was averaging four bowel movements in twenty-four hours, without admixture with blood, the arthritis and the erythema nodosum had subsided completely and she was directed to continue administration of the specific vaccine at home. In a recent letter she stated that improvement has continued.

Fig. 3. Large lanceolate diplococci within chains of smaller streptococci seen in smears from blood culture.

Fig. 4. Diplococci seen in smears from blood culture, after several subcultures in glucose brain broth. The predominating organisms here are streptococci in short chains.

COMMENT

The interesting features in the bacteriology in this case are the following: An organism like the

diplostreptococcus that was isolated from the ulcers in the rectum was isolated also from the abscesses in the tonsils. Two dissimilar organisms, both of the streptococcus group, were isolated by blood culture. The culture made from the dental abscess became contaminated, but clinical symptoms suggested relationship between this organism and that causing the arthritis. Repeated subculture of the organism isolated from the blood stream resulted in the isolation of an organism in all essentials like the organism of ulcerative colitis and also like streptococcus in short chains. In the same culture tube would appear short chains of rounded streptococci, with pairs of diplococci in the chain (Figs. 3 and 4). When the organism isolated from the blood was injected intravenously, lesions of the joints and of the colon developed. A striking feature is the isolation of similar organisms from the blood, from the abscesses of tonsils and from the ulcers in the rectum, and the temporary exacerbation of the various clinical conditions when the foci were eradicated.

One might speculate extensively about this human laboratory. The facts suggest many possibilities. The relationship of severe subacute ulcerative colitis, polyarthritis, and erythema nodosum has been described previously.[1] The opportunity of following these conditions through the various phases rarely presents itself. Information along these lines is usually gleaned from the history. This, and the bacteriologic data that accompanied each new development, must be taken seriously and applied, perhaps, in a consideration of disease on which distant foci may have a bearing.

GASTROINTESTINAL SYMPTOMS OCCURRING WITH UPPER RESPIRATORY INFECTIONS IN INFANCY AND CHILDHOOD*

EDWARD DYER ANDERSON, M.D.
Minneapolis

GASTROINTESTINAL symptoms are so often present in children having acute upper respiratory infections that it seems worth while to discuss them briefly. Often the intestinal symptoms are much more outstanding than those of the respiratory tract, so much so that one is apt to make a mistake in diagnosis unless on his guard. The intestinal symptoms frequently are so outstanding that they are the reason for calling the physician and it is only when a complete physical examination is made that the real cause of the trouble is found. It is to emphasize the necessity of making a thorough and complete examination that I wish to discuss the various intestinal symptoms which may occur with upper respiratory infections.

Any of the acute upper respiratory infections, from a simple head cold to the severest forms of influenza or pneumonia, may be accompanied by intestinal symptoms varying from those of a mild degree up to those of an alarming nature. In this paper we shall include under the term "acute upper respiratory infections," simple head colds, tonsillitis, pharyngitis, laryngitis, bronchitis, la grippe, influenza and pneumonia.

The intestinal symptoms which may accompany any one of these infections are varied. We often see any of the following: anorexia, vomiting, diarrhea, constipation, flatulence, acute abdominal pain, mucus in the stool, abdominal tenderness or tenesmus. Finkelstein and Czerny called attention to the prevalence of intestinal disturbance caused by parenteral infections, but I think that many of us fail to recognize how very frequently these disturbances occur and how severe the intestinal manifestations may be.

It is not my intention to discuss in this paper intestinal intoxication or decomposition (athrepsia) even though both of these conditions often result directly from acute upper respiratory infections. It would be impossible to adequately handle these conditions in a paper of this kind. Instead, the discussion will be limited to the type of intestinal disturbance which we all meet day after day in dealing with children.

In one group we will place infants under one year. It is in this group that one sees the most marked intestinal disturbances. It is almost always true that in babies having even the mildest head cold, the intestinal tract is upset in some way. Perhaps the most common symptom is anorexia. This may be due to two factors: first, lack of appetite due to absorption of toxin; and, second, the mechanical difficulty of nursing properly because of mucus in the nose. Most small babies who have a cold refuse to eat properly because of these two reasons. I shall not attempt to discuss the treatment of acute colds except to emphasize the importance of elevating the head of the baby so as to prevent gagging and choking and also to recommend the use of some type of nasal drop to help the breathing. Ephedrine solutions have usually proved the most satisfactory in my experience.

Vomiting is perhaps the next most common symptom and this may vary from simple regurgitation to marked nausea, with continued retching. In infants there does not seem to be any effective means of stopping this except by trying to cure the infection itself. Care should be taken not to force food. There is considerable danger that in nursing babies the mother's milk supply may diminish because of inadequate emptying of the breasts. Expression should be used to prevent this.

Diarrhea very commonly occurs in infants who have an upper respiratory infection. Usually the baby has only a moderate increase in the number of stools, and there is no serious loss of fluid or mineral salts. In these mild cases the stools usually contain mucus and they may be moderately loose. It is ordinarily unnecessary to do anything in this type of case but treat the upper respiratory infection, as the diarrhea is not severe enough to affect the baby, and it disappears as soon as the respiratory infection is cleared up.

*Read before the Upper Mississippi Medical Society, Long Prairie, Minn., Nov. 7, 1929.

Occasionally, however, one sees a baby suffering with an upper respiratory infection, in which there are frequent, watery stools and in these cases evidence of severe fluid loss soon appears. In such cases the administration of protein milk will usually control the diarrhea. This may be given either alone or the protein powder may be given diluted with breast milk, water, or a simple milk mixture. One teaspoonful of the powder given before each feeding is usually adequate. If the baby shows evidence of serious dehydration, subcutaneous fluids should be given.

Often infants with upper respiratory infections have colicky pains caused by gas or abdominal distension. Relief can be given by the use of enemas.

Older children also have gastrointestinal disturbances with upper respiratory infections, but the symptoms are usually not so marked in the milder infections, such as head colds, as in infancy. Anorexia is often present even in simple colds, but vomiting, diarrhea and abdominal pain usually do not occur except in the severer forms of infection such as tonsillitis, pharyngitis, bronchitis, la grippe, influenza or pneumonia. In these more severe infections the intestinal symptoms may be marked. Vomiting very commonly occurs at the onset of any of these infections. It may be severe, but usually lasts only a short time. Aside from the treatment of the infection, no treatment is required for the vomiting except the withholding of food until the nausea disappears. The most troublesome intestinal symptom which older children develop in these infections is acute abdominal pain.

Brenneman called our attention to the frequency of acute abdominal pain in tonsillitis. It occurs not only in tonsillitis but also in other upper respiratory infections. The pain may be severe, and, unless one is on his guard, may lead to a false diagnosis of appendicitis. This acute abdominal pain is, as we all know, very frequently present in pneumonia, particularly of the lobar type. Careful physical examination will usually make it possible to rule out appendicitis. Enemas and application of heat will ordinarily relieve the pain, except in cases of pneumonia. Here usually there is referred pleuritic pain, in which case strapping of the affected side will often give relief.

Diarrhea, although occasionally present in older children suffering with upper respiratory infections, is seldom severe enough to be a disturbing element. One sometimes sees a child with upper respiratory infection who becomes severely constipated. Simple cathartics and enemas will relieve the condition until the respiratory infection subsides and then the condition will correct itself. Abdominal distension, flatulence or tenesmus may occur, but respond to simple methods of treatment and disappear with the upper respiratory infection.

We wish finally to speak of the type of gastrointestinal disturbance so prevalent among children in the last few years, commonly called "intestinal flu," "stomach flu," "intestinal grippe" or probably more correctly called epidemic upper respiratory infection with gastrointestinal symptoms. We realize that probably none of these names is perfectly correct and that at the present time any intestinal disturbance which a child may have, from the simplest condition to the most severe, is often diagnosed "intestinal flu." Certainly this term is very promiscuously used and in fact many grave and fatal errors in diagnosis have been made because of the increasing tendency to diagnose all intestinal disturbances as intestinal influenza, regardless of the true etiology or pathology of the particular condition. In this paper we shall speak of that condition having certain definite characteristics, which to us make it a definite entity. Whatever may be the organism or other etiological factor, it seems to us that we can recognize a definite clinical picture, which for want of a better term we shall call epidemic upper respiratory infection with marked gastrointestinal symptoms. The clinical picture varies in different children but there are certain characteristic symptoms and findings which make it possible to make a definite diagnosis. The outstanding symptoms are gastrointestinal. Usually the onset is sudden, but in some cases the marked intestinal symptoms are preceded for one or two days by an ordinary head cold. The usual story, however, is that a child is taken suddenly with severe vomiting attacks. Unlike the vomiting which follows a dietary debauch of childhood and is severe for a short time, but stops as soon as the stomach is empty, the vomiting in this condition persists. The child vomits continuously and finally continues to retch when only a watery fluid is thrown up. There is rather marked prostration accompanying the nausea. The vomiting may

last from a few hours to several days, and in those cases where it persists for two or three days marked dehydration and symptoms of acidosis may appear. In other cases diarrhea may be the only intestinal symptom present, but in most cases in which diarrhea occurs it is present along with continued vomiting. The diarrhea is rather definite in character, the stools being loose, foul and almost always light in color. These colorless chalky stools are almost diagnostic of the condition. There may be a high temperature (103-104) present in the condition under discussion, but usually the temperature is of a low grade (100-101). Abdominal pain of a cramp-like and intermittent nature is very frequently present and this may persist long after the vomiting and diarrhea have stopped. The pain is generalized and there is little or no abdominal tenderness present, and no muscle spasm.

As stated above, upper respiratory symptoms may be present in the form of nasal discharge, and in some cases there is a slight hacking cough and occasionally the child may complain of a sore throat, but in the great majority of cases there are no symptoms, either objective or subjective, to lead one to suspect the presence of an upper respiratory infection. It is only on physical examination that one realizes that he is dealing with an infection of the upper respiratory tract. Invariably when the throat is examined one sees increased reddening of the pharynx, most marked around the anterior pillars. One also notices an engorgement of the blood vessels of the posterior pharynx. The tonsils (if present), although reddened, are usually not swollen and there is very seldom any exudate nor is there an increased amount of mucus in the throat. Occasionally one may hear evidences of bronchitis and in many instances otitis media with reddened ear drums may occur as a complication, but in the vast majority of children the only physical findings in the respiratory tract are the reddened pillars and injected pharynx.

In those cases where a leukocyte count is made one almost invariably finds a slight leukopenia.

Although the acute intestinal symptoms usually subside in from a few hours to two or three days, many children do not completely recover from the infection. Time and again a child is brought to the physician with the complaint that following one of these infections the child does not seem to return to his normal health. The mother says that the child won't eat well, tires easily, is irritable and that there are occasional days when there is vomiting, diarrhea or constipation. Also many of the children continue to complain of abdominal cramps. The child does not seem to be really sick, but drags around and has more or less vague intestinal and generalized symptoms that keep him from feeling perfectly well. This state of affairs may continue for only a few days after the acute attacks, but in some children it lasts for weeks.

In discussing the treatment of this epidemic form of upper respiratory infection with intestinal symptoms, I am simply going to describe the form of treatment that has worked out most successfully in my experience. I know that there are other methods of treatment which have proved successful with other men, but the methods I shall describe have proved most satisfactory in the cases that have been under my care. When the child shows the first signs of vomiting or diarrhea he should be put to bed and kept absolutely quiet. The more he moves around the longer the intestinal symptoms seem to last. This is particularly true with those who are vomiting. They should be kept in bed until all temperature, vomiting or diarrhea have stopped for at least twenty-four hours. As soon as the child or infant first shows signs of nausea he is given French Vichy water in small amounts (½ to 1 ounce), whenever he wants water. No regular water is given until he has been free from nausea for at least eight hours. The most effective method that I have found to stop the nausea has been the administration of French Vichy water in place of regular water.

No food is given to those children who are vomiting until there has been an interval of at least four hours with no vomiting or retching. In the children who are old enough to ask for food, nothing is given until they themselves demand it. In infants, if there has been an interval of four hours during which there has been no evidence of nausea, they are offered breast milk or their regular milk mixture, but if they do not want it, no effort whatever is made to force them. If they are old enough to get cereal, this is offered before milk. In the older children nothing but gelatin or Jello, dry toast and soda crackers are given for the first twenty-four hours after food is started. If they are still free from nausea at the end of that time, cereal, broth and

fruit juices are added. At the end of the next twenty-four hours if they are still free from nausea, they are put back on their regular diet. It is at this time that milk is first added to the diet.

No medication of any kind is given. This applies to cathartics, antipyretics and sedatives. It has been my experience that the more medicine one gives the longer the vomiting continues. There is an exception to this general rule of no medication in those severe cases where marked restlessness has occurred. In these cases, I have found chloral hydrate per rectum to be of value. Where the child is suffering from abdominal cramps I advise enemas, which almost invariably give relief. They may have to be repeated several times in the course of the day.

The treatment for those children in whom diarrhea is the outstanding symptom is essentially the same as in those with vomiting. They are given no food until they ask for it. The diet consists of gelatin, Jello, dry toast, cereal, soda or arrowroot crackers, broth and weak tea. After the first twenty-four hours if no vomiting has occurred, they are allowed milk which has been boiled for five minutes. No vegetables or fruits are given until the diarrhea has stopped. Where there is no nausea they are given regular water in large amounts in place of the Vichy water. No medication is given to control the diarrhea. Enemas are used if there is abdominal distension or cramps. Those children having either marked vomiting or diarrhea or both are carefully watched for any signs of dehydration or beginning acidosis and fluids are given by hypodermoclysis immediately when warranted.

As stated before, there are a fairly large percentage of children who, following the acute stages of this disease, fail to recover completely and continue to have more or less severe intestinal disturbances. I have found that the administration of Bulgarian or acidophilus bacilli in some form seems to act almost as a specific in this condition. Inside of a very few days the intestinal symptoms and the feeling of malaise will disappear and the child return to normal health. The simplest and most effective means of giving Bulgarian bacilli is in the form of Bulgarian buttermilk, when it can be obtained and the child can be made to take it. The youngster is given at least one pint a day and as much more as he wants. However, many children do not like it, and when their appetite is poor and they do not feel well anyway, it is sometimes almost impossible to get them to take it. In these cases I have the mother give the acidophilus bacilli in the form of chocolate covered acidophilus blocks or in the liquid cultures of acidophilus bacilli that some of the pharmaceutical houses dispense. There is no difficulty in giving the acidophilus bacilli in these ways and the results are usually very satisfactory.

In conclusion I wish to emphasize again the great frequency with which gastrointestinal symptoms occur in infancy and childhood with upper respiratory infections and the varied forms which these symptoms may present. I would call attention to the prevalence of a rather specific upper respiratory infection which has been present in this part of the country for the last few years, in which the intestinal manifestations completely overshadow those of the respiratory tract. Because of its prevalence there has been a tendency to diagnose all intestinal disturbances in children as this infection and grave errors in diagnosis have been made. One should never make a diagnosis of "intestinal influenza" or "grippe" until he is sure that he is not dealing with an acute appendix, an intussusception, typhoid fever, pyelitis or any of the other conditions which can simulate the clinical picture of epidemic upper respiratory infection with marked gastrointestinal disturbance. Failure to make a correct diagnosis may lead to disaster for the patient.

MENINGO-ENCEPHALITIS—A COMPLICATION OF EPIDEMIC PAROTITIS

E. E. Zemke, M.D.
St. Mary's Hospital
Duluth, Minnesota

PAROTITIS is usually a harmless disease, but it may present a wide variety of complications which render it, at times, extremely serious. Orchitis is the most frequent complication and usually runs a benign course. Other complications reported are epididymitis, neuritis, endocarditis, nephritis, arthritis, mastitis, ovaritis, vulvovaginitis, and meningo-encephalitis. The incidence of these complications varies with different epidemics. The epidemic recently observed in Duluth has brought to our attention three cases with meningo-encephalitic involvement, evidently an indication of an infective strain with neurotropic tendencies.

The occurrence of frank symptoms of central nervous system involvement is relatively infrequent. Gunderson[1] concludes, from a study of the epidemic occurrence of mumps in Norway during the last one hundred years, that there is reason to look upon this infection as the origin of lethargic encephalitis. He states that epidemics of mumps recur regularly every eight to ten years, and during these epidemics the occurrence of secondary encephalitis and secondary serous meningitis is observed, and occasionally primary mumps meningitis without parotitis occurs. In all, about two hundred cases have been reported, of which about sixty have been described in the English literature. The majority of the cases have been reported in France and the South American countries. Schoenthal[2] states that the occurrence of meningitis in mumps receives little mention in German pediatric literature. Acker and Casparis have summarized the literature up to 1913 and 1919, respectively. Since then not more than sixty cases have been added. As most patients recover after three to ten days illness, it is very probable that the meningeal condition is lost sight of, particularly in the milder cases, and this very likely accounts for the fact that so few are on record and so little is known of this complication. The symptoms may occur before or after the parotid involvement, but they usually occur at the height of the disease. In two of our cases the meningo-encephalitic involvement was the only manifestation of mumps. Howard[5] reports three, and Wallgren[6] reports two such cases.

The symptoms of meningo-encephalitic involvement may vary a great deal, but usually consist of a rise in temperature, headache, nausea and vomiting (at times projectile), stupor, prostration, and nervous hyperirritability. Del Sel,[7] Walker,[8] Wallgren,[6] Shoenthal[2] add bradycardia to the above common symptoms. Joltrain[9] calls bradycardia a characteristic. This was not manifested in our cases. Photophobia, unilateral or bilateral deafness, monoplegia, hemiplegia, aphasia, speech disturbances, and psychic disturbances may be other expressions. Objective findings may reveal a positive Kernig and neck rigidity. Wallgren reports an instance of facial paralysis and also right arm and leg paralysis with recovery. Larkin,[10] in a report of two cases, described one case of paralysis of the left arm and the right leg. In the cases reported the complication appears more frequently in males than in females.

The spinal fluid findings are quite characteristic and with the history are diagnostic. In general, the authors agree that there is a clear or slightly cloudy fluid with increased pressure and a cell count of 20 to 2,000 with a predominance of lymphocytes (80 per cent or over). No microörganisms are found on smear or culture, but a slightly positive Nonne is present. Larkin reports two cases with normal spinal fluid, while Haden[11] and Howard[5] each report two cases with gram-positive diplococci. Blood findings usually are normal, but there may be a leukocytosis up to 18,000 with a percentage increase of lymphocytes. The temperature rarely is elevated above 103.8°. The few necropsies which have been recorded have shown a very marked congestion of the brain with a serous meningitis.

M. H. Gordon[12] injected ten monkeys intracerebrally with a bacteria-free filtrate from an uncomplicated case of mumps. Four of the ten

monkeys developed symptoms of nervous disturbance and died in three to nine days. The postmortem examination was negative grossly except for fatty changes in the kidney tubules and congested areas in the liver. No pus was found in the central nervous system, but some congestion was present. Section of the cord showed a variable degree of infiltration in the pia arachnoid with lymphocytes, as well as hyperemia. A certain proportion of nerve cells, both in the cortex and in the anterior horn cells of the cord, showed pronounced degenerative changes.

The diagnosis is not difficult when epidemic parotitis accompanies or precedes the symptoms of central nervous system involvement, and when one finds the rather typical spinal fluid findings. It is, of course, more difficult when no parotitis is present, but in the presence of a mumps epidemic and direct exposure in a non-immune person, with the spinal fluid findings and the short convalescence, particularly after spinal drainage, one is almost certain as to the diagnosis.

In the differential diagnosis one must consider tuberculosis, epidemic cerebrospinal meningitis, and epidemic encephalitis.

SPINAL FLUID FINDINGS

Date	Amount	Pressure	Appearance	Number of cells	Pereentage of lymphocytes	Nonne	Smear and Culture
1/28	5 c.c.	Normal	Sl. Hazy	—	89	—	Negative
1/29 a. m.	15 e.e.	Normal	Hazy	680	86	trace	Negative
1/29 p. m.	15 c.c.	1+	Hazy	562	95	—	Negative
1/30 a. m.	25 e.e.	1+	Sl. Hazy	689	88	—	Negative
1/30 p. m.	15 c.c.	1+	Clear	540	87	trace	Negative
1/31	10 c.c.	Normal	Clear	544	—	—	Negative

CASE REPORTS

Case 1.—G. C. C., a schoolboy, aged 11, was admitted to the hospital on the serviee of Dr. C. O. Kohlbry, January 28, 1929. There was no definite history of mumps, but an epidemie existed and a history of probable contact.

Present Complaint: (1) Frontal headaehe; (2) fever; (3) nausea and vomiting; (4) hyperirritability; (5) general malaise.

Present Illness: The mother stated that the patient was chilled on January 26. He was put to bed because of a severe headache and the eomplaint of light hurting the eyes. The child was also very irritable. On January 27 the headache persisted with some projectile vomiting and high fever.

Past History: The child had had whooping cough, measles, scarlet fever, chicken pox and tonsillectomy.

Physical Examination: The patient was a well developed, well nourished boy, restless and apparently extremely sick. The eyes reacted to light and aceommodation, the eye grounds being entirely negative. The throat was somewhat injected and there was some rigidity of the neck museles. Reflexes were normal throughout. The Kernig and Babinski reflexes were negative. The temperature on admittanee was 101° F. but rose to 103° F. in the afternoon. Spinal puncture yielded 5 e.c. of a elear fluid.

Laboratory: Blood and urine were normal.

Course and Treatment: On January 29, his temperature was 103.4 F.; there was a slight Kernig reaction, some headache and marked irritability. Spinal puncture was performed at 10 a. m. and 6 p. m. On January 30, temperature reached 103 F., headache was intense, there was pain in the eyes and the neck was rigid. The Manteau and Von Pirquet tests were negative. Spinal puneture was done at 11 a. m. and 10 p. m. On January 31, the temperature was 102.2 F., neck stiffness was unchanged, Kernig's sign was definitely positive. Spinal puncture was done. On February 1, temperature was 100.6 F., neck rigidity less, Kernig less marked, and patient feeling much better. *X*-ray of the lungs showed calcified glands in the left hilum. On February 2, temperature normal, no neck rigidity, Kernig negative, and patient feeling much better. The patient was discharged the same day.

Case 2.—W. B., a male, aged 17, was admitted to the hospital April 19, 1929, on the service of Dr. F. J. Hirschboeek.

Present Complaint: (1) Delirium; (2) amnesia for past two weeks.

Present Illness: On April 4 the patient was taken ill with mumps. He went to work the next morning, but returned home in the afternoon because of headache, nausea and vomiting, feverishness, and lethargy. Patient was put to bed on April 5, and since then remembers nothing about his illness. He was sent to the hospital for observation and treatment.

Past History: Patient had had measles, whooping eough and chicken pox.

Physical Examination: The patient was a fairly well developed and nourished young male, lying comfortably in bed. The eyes reacted to light and accommodation. The eye grounds showed slight increase in redness of the disc and retina. The throat was slightly injeeted. The examination was otherwise negative. The temperature on admittance was 97.6 F.

Course and Treatment: On April 19, spinal puncture showed a cell count of 55, lymphocytes predominating; Nonne showed a trace; eolloidol gold eurve was negative; Wassermann negative. The patient improved rapidly after spinal puncture and was permitted to go home two days later, apparently in good condition.

Case 3.—M. S., a male, aged 36, was admitted to the

hospital on April 17 on the service of F. J. Hirschboeck.

Present Complaint: (1) Fever; (2) headache; (3) nausea and vomiting; (4) general malaise; (5) tenderness in right testis.

Present Illness: Symptoms began on April 10 with general malaise, chills, fever and sweats. Two days later he developed a generalized pain which became more severe in the abdomen and head. Vomiting has persisted for the past two or three days, and a mild diarrhea with increase of fever developed.

Past History: Tonsillectomy; had contact with mumps. One child in family has mumps. No other sickness was present in the community.

Physical Examination: The patient was a well developed, well nourished white male, lying fairly comfortable in bed. The eyes reacted to light and accommodation. There was no tenderness of the parotids. The throat was slightly injected and there was a slight rigidity of the neck muscles. There was some general tenderness in the epigastrium with a suggestion of a spasm on the right side. The right testis was definitely tender, but there was no marked enlargement. The reflexes were normal. The temperature on admittance was 101 F. The blood and urine were normal.

Course and Treatment: On April 18 the temperature was 102.2 F. The patient felt better and the abdomen was less tender. There was still a slight rigidity of the neck muscles. On April 19 the temperature was 102 F. A spinal puncture showed 20 cells, mostly lymphocytes; the Nonne was positive; the colloidal gold curve was 000011100. He felt much better after the puncture.

On April 20 the temperature was normal and there was no headache or neck rigidity. He was discharged April 21, feeling perfectly well.

SUMMARY

Case 1 showed no definite relationship to mumps aside from the presence of an epidemic and exposure to infection. The usual symptoms, physical findings, spinal fluid findings, and the rapid recovery with spinal puncture suggest the diagnosis. Case 2 gives a history of definite parotid involvement, following which the meningo-encephalitic manifestations were expressed by delirium and amnesia, which cleared up promptly with spinal puncture. Case 3 gives a history of mumps in the family and an orchitis with meningeal symptoms which cleared up promptly with spinal puncture.

From these cases and review of the literature, mumps meningitis seems to be an infrequent and unusual complication. It is usually manifested in the epidemic type rather than in the sporadic type of parotitis. The spinal fluid is either clear or slightly cloudy, with an increase in cells from 20 to 2,000 with a predominance of lymphocytes. Age seems to play a large part in the degree of cellular reaction shown by the spinal fluid in case 1, and the adult cases 2 and 3.

The diagnosis is made on the following:

1. The meningeal symptoms in the presence of parotitis or orchitis or an epidemic of parotitis usually beginning insidiously with a headache, vomiting, hyperirritability, general malaise, and some fever.

2. The spinal fluid findings and the relief obtained by spinal puncture.

3. The well-being of the patient during the course, which is very short.

4. The rapid recovery, which is usually complete. The treatment is spinal drainage.

For the privilege of studying these cases and for helpful criticisms the author is obligated to Drs. F. J. Hirschboeck and C. O. Kohlbry.

THE RECTAL EXAMINATION AND THE CONCEALED SECOND STAGE OF LABOR

R. T. LaVake, M.D., F.A.C.S.
Minneapolis

THE purpose of this paper is to point out a potentially serious danger in the rectal examination, namely, the danger of overlooking a concealed second stage of labor.

The following question immediately suggests itself: If a serious danger is resident in the rectal examination, why counsel its use when a vaginal examination permits greater accuracy of diagnosis? This question can be satisfactorily answered only after a thorough consideration of the relative merits of the rectal and vaginal examinations.

As far as I know, it has never been proven that, with any approximation to care in technic, the rectal examination can introduce bacteria into the vagina. From this standpoint it may be considered as harmless as no examination. If pathogenic bacteria are already in the vagina at the beginning of labor, due to an infected cervix or due to their introduction by intercourse, digital examination, septic douche nozzles, douches, etc., within a few days prior to labor, the rectal examination cannot be expected to protect the patient from the likelihood of a postpartum infection. In such a contingency, it has been objected that by a rectal examination one will smear the pathogenic flora over the inside of the cervix. The mechanism of normal labor is open to the same objection because the advance and recession of the presenting part and the bridge of membranes must tend to spread the vaginal flora. It is likely that in any labor, as soon as the cervix dilates and the cervical plug of mucus is dislodged, the vagina and uterus become one cavity and act as a Petri plate as regards extension of bacteria, modified of course by the flow of discharges and the bactericidal character of the secretions. The work of J. Morris Slemons[1] on placental basteremia tends to substantiate this likelihood; also the statistics of increased likelihood of infection following the performance of cesarean section late in labor and after the rupture of the membranes even when no vaginal examinations have been made. No bacteriologic proof has been offered, to my knowledge, of the spreading of bacteria by the rectal examination. However, statistics exist that suggest that no examinations in labor may be less productive of postpartum rise of temperature and infection than the rectal examination. Even if this were certain, the fact remains that, in the course of teaching and practice, a comparatively few cases can be allowed to go without a pelvic examination because of the demands of diagnosis, of following the progress of labor, and of handling the problem of alleviation of pain in labor.

Ralph A. Reis,[2] in an analysis of 271 cases examined by rectum only and 106 cases where no examinations were made, recorded the following findings:

AFEBRILE CASES

All cases

No exam.	56%
Rectal	46%

Spontaneous cases

No exam.	64%
Rectal	54%

PELVIC INFECTIONS

All cases

No exam.	4.7%
Rectal	6.3%

Spontaneous cases

No exam.	4.9%
Rectal	6.6%

To my mind the figures of Reis point more clearly to the importance of prenatal care than to a clear deduction of the advantages of no examination over the rectal examination.

Concerning the vaginal flora of pregnant women and the potential danger of the vaginal examination we have much evidence at hand.

In 1894, Krönig[3] concluded from a study of 100 pregnant women that "the vaginal secretion of pregnant women who have not been examined, no matter whether normal, pathological, or highly pathological, never contains organisms which grow aërobically upon the ordinary media at the body temperature except yeast and gonococci and therefore never contains septic bacte-

ria." "The vagina of every pregnant woman who has not been examined is therefore aseptic."

In the same year Krönig[4] demonstrated that the vaginal secretion possessed a marked bactericidal action upon pathogenic organisms when introduced into the vagina and stated that "we may consider the vagina of a pregnant woman as aseptic if we are sure that two or three days have elapsed since she was touched."

In 1898 J. Whitridge Williams[5] published a report on the bacteria of the vagina and their practical significance based upon the bacteriological examination of the vaginal secretion of ninety-two pregnant women. His conclusions were:

1. "We agree with Krönig that the vaginal secretion of pregnant women does not contain the usual pyogenic cocci, having found the staphylococcus epidermis albus only twice in 92 cases, but never the streptococcus pyogenes or the staphylococcus aureus or albus.

2. "The discrepancy in the results of the various investigators is due to the technic by which the secretion is obtained.

3. "As the vagina does not contain pyogenic cocci, auto-infection with them is impossible; and when they are found in the puerperal uterus they have been introduced from without.

4. "The gonococcus is occasionally found in the vaginal secretion and during the puerperium may extend from the cervix into the uterus and tubes.

5. "It is possible but not yet demonstrated, in very rare instances, that the vagina may contain bacteria which may give rise to sapremia and putrefactive endometritis by auto-infection.

6. "Death from puerperal infection is always due to infection from without and is usually due to neglect of aseptic precautions on the part of the physician or nurse.

7. "Puerperal infection is to be avoided by limiting vaginal examinations as much as possible and cultivating external palpation. When vaginal examinations are to be made, the external genitalia should be carefully cleansed and disinfected and the hands rendered as aseptic as for a laparotomy. Vaginal douches are not necessary and are probably harmful."

To paragraph 6 of Dr. Williams' deductions I would like to add, intercourse within a few days of labor, manual vaginal examinations by the patient, and unsterile douche nozzles and douches. I have felt justified in attributing many cases of sepsis to each and every one of these causes, where no examinations or operative procedures of any kind had taken place during labor and the preparation of the patient and the delivery technic and postpartum care were apparently as nearly perfect as possible. Postpartum sepsis following spontaneous deliveries during which no examination, or rectal examinations only were used, I believe to be attributable to infractions of prenatal care instructions or to failure to give any prenatal care instructions.

In 1902 Hjalmar Bergholm[6] published a most searching bacteriologic study of the vaginal secretion in pregnancy. His conclusions coincide with those of Krönig and Williams as regards the sterile character of the vaginal secretions in pregnant women. He states that "neither the staphylococcus pyogenes albus or aureus nor streptococcus pyogenes nor bacillus coli, is to be found in the vaginal secretion of the pregnant woman. The flora of the vulvar secretions is materially different from that of the vaginal secretions."

All these investigations permit one to feel with a large degree of assurance that, barring the presence of gonorrheal infection, meticulous prenatal care should bring the pregnant woman to labor with a sterile vagina. The consideration from the beginning of labor is to keep it sterile. Many of us believe that the rectal examination will do this, barring lapses in aseptic technic in the preparation of patient for labor and in the conduct of labor and the puerperium.

In this regard, what do we know about the safety and the potential danger of the vaginal examination conducted under strict aseptic technic?

We know of course that the better the technic the less chance there is of introducing infection into the vagina. Striking proof of the benefit of refinements in technic is brought out in the 1913 reports from the Sloane Hospital for Women, New York City. In these reports Dr. E. C. Lyon, Jr., showed that the routine use of the sterile rubber glove in vaginal manipulations markedly reduced the incidence of sepsis. In 16,000 cases before rubber gloves were routinely used, the incidence of sepsis was 1.13 per cent. In the last 12,000 cases in which the sterile rubber gloves

were routinely used the incidence was .61 per cent.

The most striking bacteriological demonstration of the potential danger of the vaginal examination can be found in a comparison of the researches of J. Whitridge Williams[7, 5] in 1893 and 1898. In his earlier work Williams found pyogenic cocci in the vagina in 53 per cent of his cases, including 20 per cent streptococci. In his later work, he found pyogenic organisms in only 2 per cent of the cases and not a single streptococcus. Williams' explanation of these differing results is, "the only explanation which suggests itself is that in the first series of cases bacteria, which were upon the labia minora and the margins of the hymen, were carried into the vagina by the introduction of the speculum and were then demonstrated in the cultures, while in the present series that possibility was avoided." The speculum referred to was a sterilized cylindrical glass speculum about two centimeters in diameter. In other words, it was about the size of the examining finger.

The potential danger of the vaginal examination suggested itself to Slemons[5] in his work on placental bacteremia.

The potential danger of the vaginal examination is apparent in the comparative statistics of cesarean section without and with previous vaginal examinations.

As regards the actual statistical data concerning the relative safety of the aseptic vaginal and the rectal examination, one cannot find many large series in literature.

Pfleiderer[8] cites Jegge (Basel) as having compared 500 cases examined vaginally with 500 cases examined rectally. Those examined vaginally developed temperature in 11 per cent of cases as against 6 per cent with the rectal examination.

Guggisberg[9] presents compelling figures from the Poliklinik at Bern.

1902-1911

Cases examined vaginally	4,642
Temperature reached 37.5	17.5%
Genital infection	11.2%
Deaths from sepsis	.12%

1912-1921

Cases examined rectally	3,010
Temperature reached 37.5	11%
Genital infection	5.5%
Deaths from sepsis	0

I have been unable to find in literature any comparative statistics equal to these statistics in point of number of cases compared in which the vaginal examination appeared to be more safe than the rectal examination.

Reis[2] compared results in 609 cases examined by vagina, 271 cases examined by rectum, 106 cases delivering without examinations.

PELVIC INFECTIONS

All cases

Rectally examined	6.3%
Vaginally examined	5.9%
No examinations	4.7%

Spontaneous cases

Rectally examined	6.6%
Vaginally examined	5.3%
No examinations	4.9%

Reis also tabulated his cases according to whether they were febrile or afebrile. Any patients showing more than one-half of a degree centigrade rise of temperature at any time during the first seven days postpartum were considered, for the purposes of this investigation, as being febrile.

AFEBRILE CASES

All cases

Vaginal only	47%
Rectal only	45%
No examination	56%

Spontaneous cases

Vaginal only	57%
Rectal only	54%
No examination	64%

Reis made this investigation in 1914 in an attempt to determine what difference, if any, in morbidity rate and infection rate occurred following the two types of examination in a well-conducted maternity. He concludes:

"It would seem, from a study of the figures presented above, that the percentage of absolutely afebrile cases is definitely increased when neither rectal nor vaginal examinations are made and conversely that the percentage of pelvic infections is definitely decreased. There appears, however, to be practically no difference between the group examined vaginally and the group examined rectally. This holds true for the percentage of afebrile cases as well as for the percentage of pelvic infections. If then, as most workers agree, the rectal examination is only 90 per cent efficient for diagnosis, and if it is especially inadequate in abnormal and pathological cases,

it would seem that at least one vaginal examination is desirable early in every case of labor, particularly since there is no increased danger of infection from such an examination if carefully and properly done. That the number of vaginal examinations should be limited as much as possible is self-evident from a study of the figures presented.

"The rectal examination is, however, of value in observing the progress of labor and should supplement the initial vaginal examination. The rapidity and ease with which the rectal examination can be made recommend it strongly, but it does not seem that the rectal examination should replace the vaginal examination, especially in a well-conducted maternity where vaginal examinations can be made under aseptic conditions."

In the early part of his article Reis says: "In this series, the majority of cases was examined vaginally because the routine care of service cases in the Michael Reese Maternity required one careful vaginal examination immediately upon admission and preparation of the patient. The only exceptions to this routine are cases of appreciable vaginal bleeding or patients whose histories, measurements, or abdominal examination might indicate the possibility of a cesarean section."

After viewing from all angles the results of bacteriologic research, and all comparative statistics extant at the time concerning the relative safety of the vaginal and rectal examinations, I was led, in 1913, to change from the use of the routine vaginal to the routine rectal examination. Since that time, each year's experience, in all types of situations and conditions, has added to my conviction that the rectal examination is potentially the safer examination and that the vaginal examination, under the most meticulous aseptic technic, should be used only when the rectal findings leave one in doubt. It is my belief that the universal teaching and use of the rectal examination, considering all types of conditions surrounding the obstetric patient, would reduce the incidence of postpartum sepsis.

The following advantages are resident in the rectal examination:

1. With any approximation to care, the rectal examination cannot introduce bacteria into the vagina.

2. The sterilizable rubber glove, combined with ordinary cleanliness and gentleness, makes it possible for even the most inexperienced student to conduct the examination without danger to the patient.

3. Without any increase in danger to the patient, the rectal examination permits of repeated examinations in all types of surroundings irrespective of any limitations offered by the examiner's training and perfection in aseptic technic.

4. It permits of repeated examinations with a great saving of time to the attendants and the examiner and with a great saving of inconvenience to the patient because of the fact that the rectal examination does not require the elaborate preparation for its performance necessitated by the aseptic vaginal examination.

5. Its teaching and use seems to emphasize the potential danger of the vaginal examination and stimulates all attendants to use as careful methods of preparation for performance of the vaginal examination as should be called for in the preparation for any obstetrical operation.

6. In over 95 per cent of cases that will terminate spontaneously, the rectal examination, in conjunction with the abdominal examination, will meet all the requirements of teaching and practice by giving all the data necessary for diagnosis, for following the progress of labor and for scientifically handling the problem of the alleviation of pain in labor.

7. In any case in which only rectal examinations have been used, if the necessity for interference arises we can institute said interference with the assurance that the rectal examinations have not introduced pathogenic bacteria into the vagina. Especially is this of great importance in cases complicated by antepartum hemorrhage and in those cases in which from the history, physical, and measurements we suspect that a cesarean section may be indicated with or without a test of labor.

The present-day knowledge, among educated people, of the danger of infection in labor makes the use of the rectal examination a source of reassurance to the patient and her family. When only rectal examinations have been used, if a postpartum rise of temperature takes place, the physician and the patient's family can have an increased feeling of security engendered by the fact that no infection could have been introduced

into the vagina by the rectal examination. To me this feeling of greater security following a delivery without vaginal manipulations is of great value because it acts as a source of confidence in the ultimate outcome of the case and decreases the strain of practice.

There are certain basic elements in the technic of the rectal examination that are of great importance in rendering it without danger.

First and foremost, the gloves used should be boiled so that no infection can be taken from case to case. The hands should be washed and dried, the gloves drawn on the examining hand and plenty of sterile lubricating jelly or vaseline applied to the examining finger. One must be careful not to frustrate the nursing technic of keeping the external genitalia clean. The examiner must be careful to keep away from the vulva. It is easy for the thumb of the examining hand to come in contact with the vulva or even enter the vagina if one is not aiming to avoid such a slip.

Although it is conceivable that one could be so careless and rough as to injure the anus and rectum, I have never seen such an injury. Even to the uninstructed, gentleness suggests itself, or is suggested by the patient.

It is unquestionably true that it is more difficult for the student to master the rectal examination than for him to master the vaginal examination in respect to accuracy of findings. But this difficulty is largely offset by the increased number of examinations he is allowed to make and therefore by his increased experience. My experience has taught me that the best way to initiate teaching in the rectal examination is to initiate it in the gynecologic and obstetric outpatient department, where on all gynecologic cases and on all pregnant cases in the early months the rectovaginal examination may be made and the student can check up his rectal findings by his findings with the vaginal finger. In this way he soon learns to delineate the cervix and appreciate its varying consistency and he soon learns the feel of an external os that will admit the finger. He also learns to appreciate any slight difficulties offered by the rectovaginal septum and the rectal valves. By the same token, rectal examinations alone, of patients in the last six weeks of pregnancy, especially in multiparæ, are most instructive because in many of these cases the presenting part is easily felt and obliteration of the cervical canal and even dilatation has in many instances gone far enough to be distinctly manifest. If a student has had this practice he will soon master the rectal examination in labor. The potential accuracy of the rectal examination was impressed upon me lately when, in going over four hundred consecutive labors, I found that no vaginal examination had had to be used in spontaneous deliveries and in operative deliveries the preliminary vaginal check had substantiated the rectal findings.

All errors associated with a diagnosis by rectum of complete dilatation of the cervix have been in my experience without serious consequence. We have all likely experienced the inconvenience of being called by an intern and found the patient prepared and draped for immediate delivery and, when nothing happened, discovered upon rectal examination that he had not reached far enough to find the os and had mistaken a well obliterated cervical canal with a slight dilatation of the external os for complete dilatation. This mistake, though inconvenient, could cause no harm. We have all no doubt experienced the mistake of diagnosing complete dilatation in the presence of a tissue paper cervix with a pinpoint os. I have seen this mistake made with a vaginal examination and the mistake recognized only after visual examination with a speculum. Again, this is a mistake of little consequence because with no advance, after an arbitrary two or three-hour period, the vaginal examination will have checked up our error.

The only serious error that I have seen resident in the rectal examination is associated with the diagnosis of an undilated cervix. It is a serious error in the interpretation of rectal findings that may lead to disaster from incorrect management. This error consists in overlooking what I have come to designate as a concealed second stage of labor. Call this condition what you will, the rectal findings should lead one to suspect it and corroboration should be sought in the vaginal examination.

The rectal findings consist in a peculiarly soft cervix that hangs down from the presenting part like the open end of a bag; the cervical canal is obliterated but the external os does not appear to be completely dilated; and one is surprised at the ease with which one can pull the cervix from side to side in the attempt to palpate the directing features of the presenting part. During a

pain the cervix may disappear, only to appear again between pains. This is the cervix that may be found upon vaginal examination to be potentially completely dilated and offering no obstruction to the descent of the presenting part.

These findings are present most frequently in conditions interfering with complete flexion of the head or favoring extension of the head. I have encountered it most frequently in occiput posterior positions especially of the frontocotyloid variety.

It is a relatively infrequent condition, however, occurring in my observation in about one per cent of cases. However, as this makes it approximately six times more common than measurements necessitating cesarean section, at least in the State of Minnesota and its environs, and as incorrect handling may make its non-recognition as disastrous as the non-recognition of indications for cesarean section, I consider it relatively important.

The plausible explanations for these findings that suggest themselves are: that the peculiar position of the head by pressure, reflexly interferes with the normal retraction of the cervix; that actual pinching between the head and the pelvis interfered with retraction; and that both of these conditions are associated with the phenomenon that the head extends after previous flexion and jumps away from the dilated os much as a man walking on his head makes the steps by flexing and then suddenly extending his head.

The likely and usual series of events following the non-recognition of this so-called concealed second stage of labor are: the obstetrician carries the woman along in the belief that she is in the first stage of labor and, after hours or days of labor, is puzzled by the fact that there is no advance of the presenting part and no change in the cervix. Finally when signs on the part of mother or child demand interference, the real nature of the condition becomes manifest when one has to decide upon the best maneuver for the successful consummation of delivery. Unfortunately, by this time, especially if the membranes have ruptured early, version, a possible first choice, may be contraindicated and high forceps is the remaining alternative if the head is high. The end-result of course will depend largely upon the dexterity of the obstetrician, but, at best, the chances are not promising because of the condition of the child and mother. Had this condition been suspected and recognized early, it is likely that no contraindication would have existed to interfere with a deliberate choice of the best maneuver for delivery and the delivery would have been executed with the child in good condition and with the mother not exhausted and not in a debilitated condition, making her a more easy prey to any low-grade infection that might be present.

The following two cases are of interest because in each case the condition existed in two successive labors and the difference between correct and incorrect management is clear.

Case 1.—Mrs. E., twenty-five years of age, a primipara, had been well since childhood and had had a normal prenatal history. Physical examination showed no abnormalities.

Measurements: Interspinous 27.5, intercristal 29.5, external conjugate 20, right external oblique 22.5, left normal oblique 22.5, transverse outlet 8.5, promonotory not reached.

O. L. A. position. Patient at full term.

Labor began at 11 p. m. February 22, 1923.

Desultory pains were present for two days, never less than four minutes apart. The patient was sustained with necessary sleep and rest provided by narcotics and soporifics. Light nourishment.

At 8 p. m. Feb. 25th, although the cervix by rectum was distinctly felt to be undilated the patient was taken to the delivery room. No change had taken place in the cervix for hours and there was no progress in descent. By vagina the cervix was found to be potentially completely dilated. The membranes were ruptured artificially and the case allowed to proceed.

No advance occurred in two and three quarters hours. The mother became exhausted and high forceps applied. Position O. L. A. The baby was delivered dead in thirty-five minutes. Bleeding from the nose and left ear indicated a likely fracture of the base of the skull.

Total labor 72 hours, 45 minutes.

Mistakes: A concealed second stage of labor went unrecognized through rectal examination and thus the length of labor was unnecessarily increased. Forceps were chosen rather than version with the head high and little or no moulding.

Final postpartum examination showed the cervix in excellent condition; a practical check that the child was not drawn through an undilated cervix.

Same patient. July, 1924.

Labor began at full term at 5:30 p. m., July 2.

At 9 a. m. July 3, the cervix was soft and not completely dilated as determined by rectal examination. A concealed second stage of labor was considered. At 11 a. m., no change in the rectal findings as to cervix and descent of head, the patient was taken to the delivery room for a vaginal examination. Vaginal examination showed the cervix potentially completely dilated and the head high. The membranes were rup-

tured artificially, immediate version performed and breech extraction. This maneuver was performed with ease and a 9 pound 9⅝ ounce live baby delivered.

Total labor 18 hours.

This labor, I believe, was handled correctly. It would not have been had I not suspected, by the feel of the cervix by rectum, a concealed second stage of labor, and immediately checked up my findings by a vaginal examination. I explained the lack of descent of the head to be due possibly to attitude. Version broke up this faulty attitude.

Case 2.—Mrs. A., twenty-six years of age, primipara. O. L. A. position. At term.

History, physical and antepartum care history normal, except for anemia in the latter part of pregnancy that did not respond to treatment. Her hemoglobin at term was 62 per cent.

Measurements: Interspinous 26, intercristal 28, external conjugate 20, left external oblique 22, right external oblique 22.5. Transverse outlet 8.5; promontory not reached. Normal.

Labor began at 2 p. m. July 22, 1925.

On July 23, at 2:30 a. m., the cervix was soft, the cervical canal obliterated, and three fingers' dilatation. Examination showed the identical findings at 10 a. m. and again at 11 a. m.

At 5:18 p. m., the mother was exhausted and there was no change in the cervix or descent of head. A vaginal examination was made and the cervix was found to be potentially fully dilated, the membranes intact, and an O. L. A. position.

The membranes were ruptured artificially and because of the high position of the head a version and breech extraction was done. A normal 8 pound 6⅞ ounce child was delivered.

Total labor 27 hours 30 minutes.

I should have become suspicious of the concealed second stage earlier and checked up with the vaginal examination. She ran a mild postpartum sepsis and left the hospital on the thirty-first day postpartum. This twelve hours of what I believed, after delivery, to have been an unnecessary extension of labor may have been a factor in her postpartum sepsis through lowering of her resistance, especially in the presence of an anemia.

Same patient, June, 1928. At term. O. D. A. position. Again anemia in the latter part of pregnancy that did not respond to treatment. Hemoglobin 60 per cent.

Labor began at 5 p. m. At 6:15 p. m., rectal examination disclosed a complete obliteration of the cervical canal and two fingers' dilatation.

At 10:30 p. m. the cervix was very soft, there was a three fingers' dilatation, and a concealed second stage was suspected.

At 1:10 a. m. there had been no advance of the head and no change in the cervix. Vaginal examination revealed the fact that the cervix was potentially completely dilated. Membranes were ruptured artificially. O. D. A. position.

Version was chosen because of the high position of the head. Easy version was performed and breech extraction of a living child weighing 8 pounds 6⅜ ounces.

Total labor 8 hours 30 minutes.

Normal puerperium followed except for an anemia.

In this case I feel certain that the early recognition of a possible concealed second stage of labor and a vaginal check saved this woman many hours of unnecessary labor with the concomitant danger of reduced resistance therefrom.

To one experienced in rectal palpation, the danger of error in diagnosing a concealed second stage of labor by rectum when it does not exist, is only the danger of an occasional vaginal examination under the most rigid conditions of asepsis. The dangers likely to attend the nonrecognition of the condition by rectum have been stated.

In the last analysis, conditions of operative dexterity being equal, the ultimate results will depend upon one's ability to recognize a potentially fully dilated cervix by vaginal examination, because, if one attempts an extraction by forceps or a version and breech extraction through a cervix not completely dilated, he courts one of the commonest present-day causes of fetal morbidity and mortality and maternal morbidity.

SUMMARY

1. A summation of the results of bacteriological research and labor statistics bearing upon postpartum sepsis points to the conclusion that, whenever a pelvic examination is necessary in labor for purposes of diagnosis, of following the course of labor and of scientifically handling the problem of the alleviation of pain in labor, it is expedient to use the rectal examination first and the aseptic vaginal examination only in those cases in which the rectal findings leave one in doubt.

2. The greatest potential danger resident in the rectal examination is overlooking what has been called a concealed second stage of labor. In this condition the cervix, though potentially completely dilated, is easily palpated by rectum and may give the impression, to one not keeping the entity in mind, of a cervix not nearly completely dilated, and one may allow the patient to continue on in labor without making a vaginal check, believing that she is in the first stage of labor when she is really in the second stage. Unless one keeps this possibility in mind, one may not find

out his mistake until untoward signs on the part of mother and child demand interference and when, depending upon the time of rupture of the membranes, a choice of the maneuver best suited for a successful delivery may not be made, as, for instance, version with a high head, and when the conditions of mother and child are not so conducive to ultimate success as they would have been had the concealed second stage of labor been suspected and found on aseptic vaginal examination hours before.

3. The rectal findings that should lead one to suspect a concealed second stage of labor are: a peculiarly soft cervix that hangs down from the presenting part like the open end of a bag; a cervical canal obliterated but the external os not appearing to be completely dilated. One is surprised at the ease with which the cervix can be pulled from side to side in the attempt to palpate the directing features of the presenting part. During a pain the cervix may disappear only to appear again between pains. Where these findings exist, make an aseptic vaginal examination and proceed according to the indications.

CASE REPORT

COMMINUTED FRACTURE OF THE PISIFORM BONE

A CASE REPORT

JOHN FRANCIS BRIGGS, M.D.
and
ARTHUR H. PEDERSEN, M.D.
St. Paul

Fractures of the carpal bones are of rather common occurrence, but the tendency to underestimate the significance of injuries to the wrist often leads to errors in their diagnosis.

Fractures of the scaphoid and semilunar bones, the most frequent injuries of the carpals, are usually recognized and treated successfully. Lack of recognition of these fractures or improper treatment leads in the case of the semilunar to Kienböch's disease, and in the navicular bone to the progressive loss of function and crippling of an apparently normal wrist. Failure to employ the roentgenogram in these cases results in the patient's being treated for arthritis, neuritis, etc., until finally after many months the condition is recognized and heroic measures are instituted to alleviate the suffering.

Fractures of the other carpal bones are of rare occurrence; and because of their infrequency they are overlooked. The pisiform bone lying in its anterior position to the rest of the carpals is forgotten as a potential source of injury from direct trauma, hyperflexion and indirect violence. This bone differs from the rest of the carpals in its small size and method of origin. It maintains on its dorsal surface a single facet for articulation with the triquital bone. The volar surface is rough and rounded, furnishing attachment to the transverse carpal ligament, the flexor carpi ulnaris and the abductor digiti quinti. In addition, two other small ligaments arise from this bone, the pisometacarpal and the pisohamate ligaments. The lateral surface of the bone is grooved for the ulnar artery.

The mode of development of the pisiform bone is somewhat questionable, some workers believing that it represents a sesamoid bone arising in the flexor carpi ulnaris tendon, while others feel that it is representative of a rudimentary digit.

Fractures of the pisiform are of unusual occurrence, but may be the source of a disabled wrist. R. B. Deane reports a case in a twenty-three year old male who believed he had sprained his wrist. Engel also reports a case of fracture of the pisiform bone in a sixteen year old youth who had sustained an injury to his wrist; he also cites a case of Pfab's in which ossification of the fractured pisiform bone failed to take place and the bone had to be removed. Jean and Solcard report a case of fracture of the pisiform bone in a sailor and call attention to the case reports of Buybout in 1847 and of Alsberg in 1908. Jean in 1924 treated a second case of pisiform fracture in a workman who had been injured in a sixty-foot fall.

Undoubtedly there are more cases of pisiform fracture in existence which have not been reported, but we feel that the rarity of the condition warrants the recording of the following case.

The patient, J. D., forty years of age, was sent to us on July 8, 1929, because of pain in the right wrist and difficulty in moving his right small finger. He stated that while working at Aitkin, Minnesota, as a bricklayer, he completed his job on July 3 and was in a hurry to remove the debris and framework on the building for the Fourth of July celebration. While stripping supports from the building the scaffold on which he stood broke and the patient fell a distance of ten feet to the ground. He landed on his right side, using his right arm to break the fall. From his description his right hand was in the state of hyperflexion when he struck the ground. He went to the local physician's office for first aid treatment and then returned to St. Paul. On his arrival he noticed that the pain in his right wrist had become much worse, and that movement of his right small finger now caused him severe pain. His past history is essentially negative except for minor injuries incidental to his trade.

Physical examination, except for the injuries sustained in this accident, was negative and irrelevant to the present condition and may be omitted. Examination of the right wrist showed it to be edematous over the ulnar region. The hypothenar eminence was also swollen. There was complete inability to ulnar flex with a ten degree loss of hand flexion at the wrist joint; extension of the hand at the wrist was normal, but caused the patient severe pain. Voluntary attempts to flex or extend the right small finger also caused the patient pain. On palpation of the wrist, finger point tenderness was found over the pisiform bone. It was present to such an extent that the patient requested that the procedure be not repeated. A tentative diagnosis of fracture of the right pisiform was made and the patient was referred for *x*-ray study.

The first plate taken showed no evidence of bone injury, but the clinical evidence was such that the patient was returned to the *x*-ray department for a second plate, with the wrist in the oblique position. The second picture revealed a comminuted fracture of the right pisiform bone.

The hand and forearm were placed in ulnar flexion and dorsal extension by means of an anterior molded splint, and were left in this position for six weeks without passive or active manipulation. Plates were used for comparison during the six weeks of treatment and with the formation of callus the splint was removed. Two days later the patient had a complete

return of function of the right wrist without any pain and was able to return to work.

Healing in the carpal fractures is hindered by the use of active or passive motion. Such treatment may result in pseudo-arthroses or cavity formation in the bone from destruction of the osteoblasts and new blood vessels that have formed in the process of bone repair.

CONCLUSIONS

1. Fractures of the pisiform bone are an unusual type of carpal injury.
2. Pisiform bone fractures may result in disability and should be considered in wrist injuries when dealing with a disability of vague etiology.
3. Treatment by dorsal and ulnar flexion with the use of an anterior molded splint usually gives a good end-result.
4. Improper treatment may result in necrosis and absorption of the bone fragments, thus bringing about permanent disability.

President's Letter

SOMETHING like a generation ago there came the anti-tuberculosis movement. It proposed to prevent the spread of tuberculosis and to discover and cure incipient cases of pulmonary tuberculosis. The county tuberculosis sanatorium and clinic quickly followed.

At that period the rank and file of the profession, though reasonably proficient in diagnostic and therapeutic skill, foolishly believing the sanatorium staff and its clinic possessed greater ability than themselves, promptly passed their patients along, lost interest in tuberculosis and directly forgot the knowledge and skill once theirs. A little later and the sanatoria and their clinics were swamped with cases in all stages of the disease, both medical and surgical. The defect in the system now became apparent in the lack of doctors in the general field sufficiently skilled to aid in taking care of these cases. Since then this defect has been largely corrected.

Now comes the heart movement. It takes form in the activities of several different organizations more or less closely allied. First comes The American Heart Association seeking to discover the incidence, causes, and prevention of heart disorder. Then comes the Public Health Association seeking to ferret out cases of heart disease, establish clinics for the treatment of same, and to find employment for the partially incapacitated. Other clinics representing lesser organizations are also in process of formation. The two major organizations, in some places at least, seek to link the heart movement with the anti-tuberculosis movement and carry on as a unit activity.

The work of these organizations so far as the study of incidence, etiology, distribution, prevention, economic aspects and emplacement are concerned is most commendable. But when their clinics appear with mass treatment of patients as a part of their work, especially when linked with the field of tuberculosis, they take a step that is ill advised, because it tends to be destructive to the scientific morale of the rank and file of the medical profession, and because a contagious and a non-contagious type of disease are linked together. Carried to its logical conclusions the effect on the profession will be the same as in the anti-tuberculosis movement, and that must not occur again.

This is the point at which the Minnesota State Medical Society steps in. Through its Heart Committee in conjunction with the committee on Hospitals and Medical Education it proposes to take an active and effective part. It proposes to see to it that its members shall have every opportunity to keep abreast of the best and most progressive heart thought and practice of the day. It is determined that its members shall not lag and lose interest in this vital subject, shall not say, "Let George do it."

The understanding of heart disorders is not difficult. The modern classifications based on etiology, structural change and function are most simple and illuminating. They are most stimulating to your interest. They pique your medical curiosity. It is along these lines the two above mentioned committees will proceed. The Heart Committee will formulate details of heart instruction while the Committee on Hospitals and Medical Education will disseminate this knowledge through its extension service.

Lend these committees your most hearty support *to the end that the clinic may not be needed* and to the glorification of yourselves and your profession.

S. H. Boyer

President,
Minnesota State Medical Association.

KARKINOLYSIN AND CANCER

In this number of MINNESOTA MEDICINE there is published an article by Dr. Adolph M. Hanson of Faribault, Minnesota, on the treatment of inoperable cancer with thymic extract. No one who is acquainted with Dr. Hanson can doubt his honesty and sincerity; and his previous work on the parathyroid attests his ability as an investigator. Four cases of cancer treated with thymic extract are reported. Case 1 is clearly an adenocarcinoma of the splenic flexure. This patient lived about four years after surgical removal of the tumor. Death was attributed to pneumonia, but there was no postmortem examination. If a cure was really effected in this case, it might be attributed to surgery.

In Case 2 the clinical diagnosis was carcinoma of the stomach, but no diagnosis can be made on the microphotograph. About one year after the exploratory operation the tumor could no longer be palpated. The patient gained in weight and was in good health when last heard from. The date when the patient was last heard from is unfortunately not given, and she was apparently not examined later than June 12, 1926.

In Cases 3 and 4 the period of observation is entirely too short to determine the efficacy of the treatment.

The author does not state whether any other cases of cancer were treated, and this is a very important omission. Are these four cases the only ones treated, or are they the only ones reacting favorably?

Dr. Hanson makes it clear that he does not claim to have discovered a cure for cancer, but he would have us believe that thymic extract is of value as a palliative treatment. But even this claim is not justified by the case histories that are reported. The clinical history of cancer is very variable. Physicians of long experience know that persons with inoperable cancer often live several years in apparently good health.

It is possible that thymic extract causes necrosis of the central part of large malignant tumors, such as is sometimes observed after treatment with radiation, lead, or Coley's toxin.

Dr. Hanson should be encouraged to continue his work, but much stronger evidence of the value of the treatment must be produced before it can be recommended to the medical profession.

MORTALITY PREVENTION IN MOTHERS AND INFANTS

The Commonwealth Fund has recently made public the results of a four-year demonstration of the value of preventive medicine in the field of prenatal maternity and postnatal infant care. The following four locations were chosen for the experiment: Fargo, North Dakota; Marion

County, Oregon; Clark County, Georgia; and Rutherford County, Tennessee. The results are striking. The total figures show that the maternal death rate, stillbirths and infant mortality under one month of age were about double in the group that received no medical or nursing care. In some of the localities the death rate in the three groups was several times as great in those who received no supervision. During the first year of life, more than twice as many infants not receiving supervision died, as in the supervised group. The diseases which accounted for the difference were for the most part enteritis, acute respiratory infections and congenital defects.

One may argue that the group which sought medical and nursing care represented the more intelligent group in each community, the mere fact of their seeking or accepting instruction indicating their higher intelligence; and that this group without medical care would have shown a lower mortality. We do not know how important this factor was in this particular demonstration but it does not seem likely that this would have accounted for the marked difference demonstrated.

The importance of preventive medicine is appreciated by most of us. The public is having it more and more impressed upon its individual members. There is evidence from time to time of a lagging in interest on the part of certain members of the profession responsible for this type of work. Examination of well infants, for instance, may in time lose its attraction to the examining physician and he may lose some of his enthusiasm. The importance, however, of proper feeding of the normal infant has become further emphasized in recent years. Proper vitamin content in the diet in maintaining an infant's maximal resistance to infection and in not only preventing manifest rickets but assuring normal dentition makes the subject all the more intriguing.

For those who require figures to be convinced of the results attainable by medical supervision of mothers and infants we would recommend a perusal of the figures submitted in this demonstration.*

FAIR PLAY

There has lately been considerable criticism of our old friend Dr. Brady, particularly in regard to certain statements made by him in regard to the indications for tonsillectomy, and the best methods of removal of healthy and diseased tonsils. Of course, it is axiomatic that no human, with the possible exception of the above mentioned columnist, is capable of gathering together in one small cranium all the Truth regarding even such a circumscribed field as that of modern medicine, let alone being able to grind it out daily for the consumption of the lay neuro- and hypochondriac. The fact that his statements hold water somewhat over 50 per cent of the time should be a cause for congratulation, rather than censure.

And when one begins to realize the subtle manner in which the financial welfare of the profession is being aided and improved by these articles we should add our heartfelt gratitude to our congratulations.

For instance, there is a well-established belief that tonsillectomies in the adult are becoming scarcer and scarcer as the years pass by, due, of course, to the fact that almost all grown-ups of the present generation lost a greater or lesser amount of their tonsillar tissue during childhood, infancy, or early youth, and, if a clean-cut tonsillectomy was done at that time, the patient is automatically protected against any further interference, and, by the same token, the profession is deprived of its right to do a secondary tonsillectomy.

Contrast this situation with that which we may expect if the good doctor is successful in his propaganda for the "electric" method of tonsil removal. In the first place, the patient can be kept coming to the office for treatments, "burning," "desiccation," "coagulation," and so forth, for almost an unlimited number of visits, and, when he does quit from exhaustion, either physical or financial, there is still plenty of infected adenoid tissue left in the tonsillar fossæ, which, when solidly sealed in by the resulting scar tissue, will almost invariably result in a mass attack on the part of the whole "itis" family, and drive the patient into the arms of a competent surgeon. Naturally, a secondary tonsillectomy through this mass of scar tissue is exceedingly difficult and the operator is certainly

entitled to a greater fee than can be honestly demanded for removing virginal tonsils.

The writer has had this condition forcibly brought to mind in two cases of recent date, whose histories are almost identical. Enlarged tonsils, and occasional sore throat. Tonsillectomy had been advised. The possessors were saved from this ordeal by the timely perusal in the morning paper of an article by our good friend, the doctor, and immediately took advantage of the "new electrical" method. After an inordinate loss of time and considerable expense, healing was at last allowed to take place, and, once solidly healed, both patients came down with a subacute arthritis which persisted until the infected foci were removed. These patients are now well, and happy to have safely passed through such a serious ordeal, and can now recall and discuss their symptoms with other sufferers, to their hearts' content.

Space will not permit discussion of the dictum that 70 per cent of all removed tonsils should have been left alone. Certainly if that high a proportion of tonsils *are* unaffected, no very harmful results can accrue from the method of electro-coagulation. The patient is no worse off than before, and his doctor is that much ahead. At the same time it has functioned as a therapeutic test which works out as follows: If the patient is no better nor no worse than before, then he is one of the 70 per cent whose tonsils did not need to be removed. If he develops symptoms of absorption following the incarceration of the tonsillar bacteria, it is definite proof of tonsillar infection and an indication for tonsillectomy. Let us be fair—and slow to criticize, for who knows when he may "bite the hand that feeds him"?

M. W. W.

HISTORICAL COMMITTEE

Will not some of you who read this stuff help stimulate the gathering of material for our History of Medicine in Minnesota? Contribute something so I shall not have to think up new things from month to month to publish here. Our own knowledge of early medical men and events is largely confined to our own city and you may become tired of it. We thought the first published medical communication came from Minnesota in 1853 and J. H. Murphy contributed a note on abscess of the breast in 1854. A few months ago, however, we found an article written in 1814 and published in 1816 by the first medical officer at Ft. Snelling, and a still shorter time ago we picked up unexpectedly Vol. I, No. 4 (January, 1859) of the "Minnesota Homœopath" published in St. Paul. We had always thought Dr. A. J. Stone's Northwestern Medical and Surgical Journal (1870) the first. After looking over the Homœopath, however, we concluded it hardly merits the name of a journal, but nevertheless it gave us an historical, not hysterical, thrill.

Write Dr. H. M. Workman, Tracy, Minnesota, if you know anything interesting. The Committee will appreciate it.

J. M. A.

THE COMMITTEE ON FOODS.

The need of some body to express judgment of food products and food advertising, in the same way that the Council on Pharmacy and Chemistry considers medical preparations, has become apparent. The Council has therefore created a special committee on foods. The manufacturers of food products, distributors and all others interested in the promotion of natural food substances or of modified foods, for which claims are made in relation to the promotion of good health, will be asked to submit to the committee the products and the advertising material used in advancing their sale. If a product is found acceptable by the committee, advertisements of it will be permitted in the publications of the American Medical Association, the product will be listed in the book on foods similar to New and Non-official Remedies, and the manufacturers will be permitted to use a symbol indicating that the product has been accepted by the committee for listing in the book of foods. If the product cannot reach the standards set forth, a report will be published as is done for drug products, and advertising of the preparation will not be permitted in the publication of the American Medical Association. The work of the Committee on Foods should do much to carry still further the message of good hygiene and of scientific medicine. In beginning this work, the Council on Pharmacy and Chemistry again asks the complete support of the medical profession. Only by the sincere coöperation of the medical profession with the committee can it achieve the prestige necessary to complete attainment of its objects. (Jour. A. M. A., October 12, 1929, p. 1147.)

A PAGE FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

State Medicine

An extremely interesting prospectus for a new project in the field of public health to be undertaken this year by the Commonwealth Fund has been sent to every state health officer in the United States and the deans of the medical schools.

This Commonwealth Fund was established ten years ago by the Steven V. Harkness fortune of Rockefeller Oil affiliations.

Education and child welfare were its original objects. But a recently established division of public health with Dr. William J. French as director has had the following proposal outlined in its main points below, as sequel.

From one point of view this fund proposes to show state health departments how they make detection and cure of disease a state function. It proposes, also, to assist in paying the bill.

Is it, in other words, just another very important step toward the establishment of "State Medicine"?

The two related lines of public service planned by the fund fall under two heads, "public health activities" and "medical service." They are to be put into effect in two or possibly three states where health departments desire and request it.

I. Public Health Activities

A. The establishment, under direction of the state health department, of a field unit for the purpose of organizing and improving county or district health service in rural areas.

B. Assistance, through the state health department, to two rural counties or districts in the state for the purpose of establishing complete health units to render public health service according to the best current standards. The minimum unit which will be considered for such assistance will include a full-time health officer, a sanitary officer, two public health nurses, and one clerk. Larger units are to be preferred.

II. Medical Education

A. Assistance to a Grade A medical school which sends a reasonable percentage of its graduates into the state in question: to develop courses in preventive medicine, and to provide special facilities and opportunities for postgraduate work by rural physicians. While this school will presumably be located in the state selected, a school elsewhere may be designated if it customarily draws students from the state in large numbers.

B. The establishment at the same medical school of a scholarship or loan fund for the use of not less than five students from the state in question who agree to go into rural practice in that state for a stipulated period after graduation.

C. The establishment of fifteen postgraduate fellowships each year for physicians in each state selected for the public health activities mentioned above, as a contribution toward raising the standards of rural medical practice. Five fellowships will be awarded in each of the counties or districts where health units are established, and five in the state at large. Appointments will be made by the Commonwealth Fund.

III. Public Health Nursing

A. The establishment of one or more postgraduate fellowships for public health nurses actually employed in the state selected.

IV. Health Education

A. Assistance to the state normal school, or other teacher-training institution, in providing facilities for the training of teachers in the purposes and methods of health education.

B. The establishment of one or more fellowships in health education to be awarded each year to teachers employed in the schools of the districts where health units are established under this plan.

This plan in its entirety is intended to be flexible and experimental. No fixed time-limit has been set for its operation. The staff of the Division of Public Health will endeavor to assist in correlating the educational projects in each state with the public health activities to the end that progress may be consistent and concrete.

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 10:15 o'clock every Wednesday morning over State WCCO, Minneapolis and St. Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of February will be as follows:

February 5, 1930—Pork worm disease
February 12, 1930—Glaucoma
February 19, 1930—Feeding the problem child
February 26, 1930—Inflammation of the ear

WHITE HOUSE CONFERENCE ON CHILD HEALTH AND PROTECTION

A conference of pretentious dimensions, the function of which will be to consider the various phases of child health, has been put under way by President Hoover. Financed by contributions from the great foundations and headed by Dr. Ray Lyman Wilbur, Secretary of the Interior, the conference is to be national in scope. Instead of consisting of a conference meeting of two or three days' duration, a number of meetings in addition to those already held in Washington, New York, Philadelphia and Boston will be held over a period of one to two years.

Committee appointments of those prominent in the profession, in public health work, nursing, institutional work, and so forth, have been made and every phase of the subject of child welfare will be included in the program. This comprises a consideration of factors influencing the child from the standpoint of heredity, prenatal care, birth, nutrition in infancy and childhood, child psychology, etc.

The following committee and sub-committee chairmen have been appointed:

SECTIONS

Section I. Medical Service, *Samuel McC. Hamill, M.D.,* Philadelphia, Pa.
- A. Growth and Development, *Kenneth D. Blackfan, M.D.,* Boston, Mass.
- B. Prenatal and Maternal Care, *Fred L. Adair, M.D.,* Chicago, Ill.
- C. Medical Care for Children, *Philip Van Ingen, M.D.,* New York City

Section II. Public Health Service and Administration, *Hugh S. Cumming,* Surgeon-General, Washington, D. C.
- A. Public Health Organization, *E. L. Bishop, M.D.,* Nashville, Tenn.
- B. Communicable Disease Control, *George H. Bigelow, M.D.,* Boston, Mass.
- C. Milk Production and Control, *H. A. Whittaker, C.E.,* Minneapolis, Minn.

Section III. Education and Training, *F. J. Kelly, Ph.D.,* University of Idaho
- A. The Family and Parent Education, *Louise Stanley, Ph.D.,* Washington, D. C.
- B. The Preschool Child, *John E. Anderson, Ph.D.,* Minneapolis, Minn.
- C. The School Child, *Thomas D. Wood, M.D.,* New York City
- D. Vocational Guidance and Child Labor, *Anne S. Davis,* Chicago, Illinois
- E. Recreation and Physical Education, *Henry Breckenridge,* New York City
- F. Special Classes, *Chas. S. Berry, Ph.D.,* Ann Arbor, Mich.

Section IV. The Handicapped: Prevention; Maintenance; Protection, *C. C. Carstens,* New York City
- A. State and Local Organizations for the Handicapped, *Mrs. Kate Burr Johnson,* Raleigh, N. C.
- B. Physically and Mentally Handicapped, *William J. Ellis,* Trenton, N. J.
- C-1 Socially Handicapped — Dependency, *Homer Folks,* New York City
- C-2 Socially Handicapped—Delinquency, *Frederick P. Cabot,* Boston, Mass.

RICE COUNTY MEDICAL SOCIETY

A meeting of the Rice County Medical Society was held in the Faribault Clinic Rooms December 11, 1929. In addition to twenty-five members of the society, Dr. C. B. Wright, Minneapolis; Dr. E. A. Meyerding, St. Paul; Dr. W. D. Beadie, Cannon Falls; Dr. Emerson, of Northfield; and Dr. D. E. McBroom, Cambridge, were present.

The meeting was called to order by the President, Dr. J. M. Murdoch, and after the minutes of the previous meeting were read and approved, and other routine business disposed of, Dr. Adoph M. Hanson of Faribault read a paper entitled "A Report of Four Cases of Inoperable Cancer Treated by Intramuscular Injections of Karkinolysin."

Dr. Hanson, after completing his pioneer work on the parathyroid gland and its calcium-raising hormone, has spent several years of research work and experimentation on the cause and treatment of cancer, and has finally reached that stage when it was deemed advisable to reveal his results thus far, for the first time, to the members of the society, in order that clinical experimental work may be carried out on a larger scale by other investigators.

Dr. Hanson does not wish to be understood as having a specific cure for malignancy, but Karkinolysin evidently has a solvent action in the cases reported of sufficient interest to report his findings to the profession.

Dr. Hanson received generous expressions of commendation for his achievement thus far in this direc-

tion, by Drs. C. B. Wright, Ex-president of the Minnesota State Medical Association; E. A. Meyerding, Secretary of the Minnesota State Medical Association; W. D. Beadie, Superintendent of Cannon Falls Sanitarium; D. E. McBroom, Superintendent State Epileptic Colony at Cambridge; and members of the Rice County Medical Society.

Dr. Murdoch, President, in behalf of Rice County Medical Society, thanked Dr. Hanson for his interesting message, and assured him the full support and best wishes of the society in his future work.

There being no further business the meeting stood adjourned.

C. J. Plonske, M.D., *Secretary.*

CONFERENCE OF SECRETARIES

Seventy-five physician-delegates representing 28 different district and county medical societies registered for the annual conference of secretaries of the Minnesota State Medical Association, held Jan. 11, 1930, at the Athletic Club in St. Paul. Dr. F. C. Schuldt, president of the Ramsey County Medical Society, welcomed the delegates.

High lights on the program of the conference included a lively discussion of the high cost of hospital care and its causes; the relation of the medical association to the current heart disease campaign; and the safe storage of inflammable *x*-ray film.

Dr. I. C. Riggin, New York, executive secretary of the American Heart Association, outlined the proposed program of the national association for the conference. Dr. N. O. Pearce, Minneapolis; Dr. F. A. Willius, Rochester; Dr. O. E. Locken, Crookston; Dr. S. A. Slater, Worthington; and Dr. J. F. Borg, St. Paul, discussed the local aspects of the campaign.

Dr. Pearce, Dr. William A. Meierding of New Ulm, and Paul Fesler, superintendent of the University Hospital, spoke on the community hospital, its organized staff and its costs.

Fire prevention officials of Minneapolis and a representative from the Eastman Kodak Company explained methods of protection for storage of the inflammable nitro-cellulose film and urged the secretaries to substitute the acetate safety variety of film for the inflammable nitro-cellulose in *x*-ray work. Dr. S. H. Boyer, Duluth; Dr. C. G. Sutherland, Rochester; and Dr. C. B. Wright, Minneapolis, related their experience with both types of film and with film storage.

Mrs. J. D. Lyon, president of the Women's Auxiliary, discussed the activities of her organization.

Interesting aspects of legal medicine and malpractice insurance encountered by F. M. Brist, St. Paul attorney for the State Board of Medical Examiners, with discussion by Dr. W. H. Hengstler, St. Paul, and Dr. H. M. Johnson, Dawson, and a review by Dr. F. H. Magney, Duluth, of the successful lay health education program carried on by St. Louis County Medical Society, also had a place on the day's program. Dr. George Earl, St. Paul, indicated the inevitable place of the practising physician in public health programs of the future.

RED RIVER VALLEY MEDICAL SOCIETY

The following officers were elected by the Red River Valley Medical Society at their annual meeting December 19, 1929:

Dr. C. M. Adkins.....Grygla.....*President*
Dr. Halvor Holte.....Crookston.....*Vice President*
Dr. C. L. Oppegaard.Crookston.....*Secretary-Treasurer*

Dr. Arthur Kahala, of Crookston, was elected censor for three years.

The following members were elected to represent the society at the state meeting for 1930: Dr. H. M. Blegen, Warren, first delegate; Dr. I. G. Wiltrout, Oslo, first alternate; Dr. O. E. Locken, Crookston, second alternate; Dr. J. F. Norman, Crookston, second alternate.

HENNEPIN COUNTY TUBERCULOSIS ASSOCIATION

The Hennepin County Tuberculosis Association held its twenty-seventh annual meeting in the Citizens Aid Building, Minneapolis, Thursday evening, January 30.

The Board of Directors met preceding the dinner to elect new officers, and during the dinner election of new Association members and new Board members was made.

Speakers, each of whom contributed to the picture of "How Our Community Is Meeting Its Tuberculosis Problem," included:

Dr. H. A. Burns, superintendent, State Sanatorium; Dr. E. S. Mariette, superintendent, Glen Lake Sanatorium; Dr. Jay A. Myers, Chief of Staff, Lymanhurst Clinic and School; Dr. F. E. Harrington, Health Commissioner, Minneapolis; Dr. Walter J. Marcley, Veterans Bureau; Dr. N. O. Pearce, president, Hennepin County Tuberculosis Association; Dr. H. L. Ulrich, chairman, Heart Committee, Hennepin County Tuberculosis Association; Dr. E. A. Meyerding, executive secretary, Minnesota Public Health Association.

TREPARSOL

Treparsol differs from the better known acetarsone in that it has a formyl group in place of the acetyl group of acetarsone. Its oral use, as with acetarsone, in the treatment of syphilis is not supported by adequate evidence. Treparsol has not been accepted by the Council on Pharmacy and Chemistry. (Jour. A. M. A., December 7, 1929, p. 1830.)

COMMUNICATION

DEPARTMENT OF COMMERCE
AERONAUTICS BRANCH
WASHINGTON

December 21, 1929.

To the Editor:

The attached resolutions were passed by the American Medical Association at its stated assembly held at Portland, Oregon, in July, 1929. It is believed that these resolutions are of sufficient interest in view of the rapidly increasing number of physicians designated as Medical Examiners to warrant publication in your journal.

You may be interested to know that all applicants for federal pilot licenses, either for flying or for training as pilots, must pass physical examinations before physicians designated by the Secretary of Commerce. They must likewise be re-examined periodically. These examinations cover a rather detailed examination of the eyes, a brief examination of the ear, nose and throat, equilibrium, a general physical examination, and a detailed examination of the nervous system. There are now about 750 Medical Examiners so designated throughout the country. All these examinations are reviewed in Washington, where the applicant is finally certified as qualified or disqualified for the grade for which he has applied.

Very truly yours,
L. H. Bauer, M.D.,
Medical Director.

Whereas, The Aeronautics Branch, Department of Commerce, has organized a medical service for the physical examinations of civil pilots and prospective pilots, in the interests of safety; and

Whereas, The physical standards adopted are in keeping with those adopted universally, and have reduced aircraft accidents from physical causes to a minimum; and

Whereas, The department has required these examinations to be made only by designated physicians in the interest of uniformity and control and in accordance with the custom adopted for the Army and Navy and in other countries; and

Whereas, The selection of examining physicians by the department has been based on training as flight surgeons or its equivalent, or on group examinations by specialists, a high standard of examination has resulted; and

Whereas, The department requires that all examiners hold the degree of Doctor of Medicine, be licensed to practice medicine under the laws of their respective states, and further requires that the appointees be recognized as ethical practitioners in their respective localities, thereby supporting the high standards advocated by this Association, be it

RESOLVED, That the American Medical Association at its stated assembly in 1929 endorses the medical work of the Department of Commerce, its methods of physical examination and its method of selection of medical examiners, and urges that the same high standards be continued and offers the support of the American Medical Association in furthering the specialty of aviation medicine; and be it further

RESOLVED, That a copy of this resolution be sent to the President of the United States, the Secretary of Commerce, and the Secretary of each state medical society.

NEW AND NON-OFFICIAL REMEDIES

The following articles have been accepted by the Council of Pharmacy and Chemistry:

E. Bilhuber, Inc.
Lenigallol-Zinc Ointment

Cutter Laboratory
Scarlet Fever Streptococcus Antitoxin-Cutter

Mead Johnson & Co.
Mead's Viosterol in Oil 100 D

H. K. Mulford Co.
Ampules Sodium Cacodylate-Mulford, ¾ grain, 1 c.c.
Ampules Sodium Cacodylate-Mulford, 3 grains, 1 c.c.
Ampules Sodium Cacodylate-Mulford, 5 grains, 1 c.c.

Winthrop Chemical Co., Inc.
Tablets Tutocain No. 6

The following article has been exempted and included with the List of Exempted Non-medicinal Articles (New and Non-official Remedies, 1929, p. 485):

Child Welfare Guild, Inc.
Bite-X

TRUTH ABOUT MEDICINES

Gelatin Compound Phenolized-Mulford.—A mixture composed of gelatin, zinc oxide, glycerin, and water, containing 1.5 per cent of phenol. It is used in the preparation of bandages to cover chronic ulcers, unhealed secondary burns, and in the preparation of pressure bandages for varicose veins, when surgical treatment is not necessary. H. K. Mulford Co., Philadelphia.

Diphtheria Toxoid-Mulford, 30 c.c. Vial.—Diphtheria Toxoid-Mulford (New and Non-official Remedies, 1929, p. 369) is also marketed in packages of one 30 c.c. vial. H. K. Mulford Co., Philadelphia.

Typhoid-Paratyphoid Prophylactic, Hospital Packages.—Typhoid-Paratyphoid Prophylactic (New and Non-official Remedies, 1929, p. 379) is also marketed in hospital size packages containing ten complete immunizations. Cutter Laboratory, Berkeley, Calif.

Ampule Solution Silver Nitrate 1 Per Cent-Cutter.—Solution silver nitrate 1 per cent, approximately 0.2 c.c., contained in ampules composed of beeswax. They are used for the prevention of ophthalmia neonatorum. Cutter Laboratory, Berkeley, Calif.

CONSULTATION BUREAU

WM. A. O'BRIEN, M.D., *Director*
Minnesota State Medical Association
11 West Summit Avenue
Saint Paul, Minnesota

1. *Question.*—I have a patient, a nine year old boy, who complained of intermittent aching pain in the right shoulder. There was no history of injury. Physical examination was negative except for slight tenderness in the upper end of the humerus. There was no limitation of motion of the shoulder joint. *X*-ray examination was thought to show a separation of the epiphysis of the humerus. A cast was applied and kept on for several weeks. When it was taken off, a second *x*-ray examination revealed practically the same change as was seen in the first. In the interval, however, he had been entirely relieved of all symptoms. This followed in a few days after the cast was applied, and when the cast was taken off he said that his arm was all right and felt as well as ever.
   Was there a true separation of the epiphysis? Should the cast have been left on longer?
   Answer.—The fact that the two *x*-ray plates were the same and all symptoms were relieved probably indicates no epiphyseal separation was present. The relief of pain by the use of a cast suggests that there was an epiphysitis, an arthritis, or some other type of inflammation of the shoulder joint. No further treatment is necessary.
2. *Question.*—I am desirous of getting information about a drug known as "Yatren." What is its value in the treatment of any form of colitis? Is free purgation following two to four pills four times daily a concomitant of its use, or more likely related to the colitis? Is it indicated in amebiasis? Is it merely empirical, or is it accepted?
   Answer.—"Yatren" is a drug which is specific for the destruction of amebæ. Its use in other forms of colitis is not recommended. The continuation of the colitis after the use of "Yatren" probably indicates that the lesion was due to some other factor. The drug is recognized and widely used. Have you examined the stools for amebæ, or is the patient suffering with nonspecific ulcerative colitis or a form due to the normal flora of the bowel? If no amebæ are present and the colitis is of the nonspecific type, it is doubtful if "Yatren" would have any effect.
3. *Question.*—I saw a patient not long ago with a red edematous mass which started with the left trapezius muscle and extended over the clavicle down the chest to the fourth rib and straight across and up the other clavicle to the right trapezius muscle. The spaces above and below both clavicles were evenly filled with this edema and were very tender to touch. Patient was clear mentally, and had no chills or sweats. Morning temperature ranged from 100 to 101; afternoon, 102. Leukocytes 20,000. Pulse 90 to 102.
   When first seen, patient had no edema but complained of intense pain. She was not able to stand it without morphine. Shortly after this, the edema started and spread as described, but did not affect either the neck or shoulder joints. She admitted that she had cut herself slightly a few days before while butchering hogs. Had used no antiseptic as it did not bleed. This area had become very tender; was covered with a bleb when I saw it. Applications of cold were made to the edematous part, which reduced it considerably. I thought of the possibility of erysipelas and gave the serum, with the resulting drop of temperature. Condition remained fairly stationary for a day or two, and then recurred. Should this lesion be opened by multiple incisions?
   Answer.—The most probable diagnosis is cellulitis. No pus is present in the more virulent forms. The most one can expect after opening is a little thin, cloudy fluid, but even this may be absent. A smear or culture of the region would reveal the causative organism. Wide and free drainage might help.
4. *Question.*—I have a patient, a middle aged woman, who has been sick for the past three weeks. She complains of sharp epigastric pain, nausea and vomiting, and moderate prostration. She has no chills, fever, or sweats. There is no jaundice or other signs of obstruction of common bile duct. She is an obese individual and has never had trouble like this before. An *x*-ray of the stomach and duodenum shows no signs of ulcer. An *x*-ray of the gall-bladder region is also negative. The pain, which is very sharp, usually comes on about three or four o'clock in the morning and interferes with sleep. The first few nights, I think, she had some relief from food. I have had her on ulcer management, but this does not seem to help her any. The patient also complains of some pain in the daytime, but this is not as marked as the night pain. She vomits a great deal with the attacks.
   What are the other diagnostic possibilities and what should be done to relieve the condition?
   Answer.—In an obese woman, the possibility of para-esophageal hernia should be considered. An article on this subject appeared in a recent number of MINNESOTA MEDICINE. Hernia at the esophageal hiatus cannot be diagnosed clinically. As a rule, it is necessary to make an *x*-ray examination with the patient in the recumbent position. This allows the stomach to slip up in the opening and may reproduce the attacks the patient describes. Pancreatitis is another possibility. Swelling of the pancreas might be visualized if the duodenum is widely separated. Clinical diagnosis of pancreatitis is rather vague and cannot be made with any certainty. I would advise you to investigate the possibility of diaphragmatic hernia. If this is present, it is possible to operate on the patient and sew up the hernial opening.

OBITUARY

Paul Frederick William Wipperman

1888-1930

Dr. Paul Frederick William Wipperman, well known to the profession in Minnesota, died on the morning of January 2, 1930, following a month's illness due to a streptococcic infection. At the time of his death he was superintendent of the Touro Infirmary at New Orleans.

Dr. Wipperman was born November 26, 1888, on his grandfather's farm in Warren County, Missouri, the son of a Methodist minister. He received his degree of A.B. from the Central Wesleyan College at Warrenton, Missouri, and then worked his way through the medical school at the University of Minnesota, where he graduated in 1913. While at the medical school he played on the basketball team for three years and captained a championship team his Senior year.

After serving his internship in the Minneapolis General hospital Dr. Wipperman began practice at Albany, Minnesota. In 1915 he became medical examiner for the Twin City Rapid Transit Company and in 1917 enlisted as Lieutenant in the Medical Corps, which took him to Fort Riley and San Antonio. Upon being mustered out of the army he organized the Veterans' Service Clinic in Minneapolis and in 1922 was appointed commanding officer of the U. S. Veterans' Hospital No. 30 at St. Louis. From 1923 to 1928 Dr. Wipperman superintended the Decatur and Macon County hospital in Illinois and for the past year has been the head of the Touro Infirmary in New Orleans.

Dr. Wipperman is survived by his father and mother; one sister, Mrs. Ernest Sears; his wife, formerly Miss Erna Snell of Fairfax, Minnesota; and a son, Frederick.

H. N. Hovde

1861-1929

Dr. H. N. Hovde, aged 68, prominent practising physician at Duluth, Minn., died suddenly from a heart attack Dec. 24, 1929, while attending a patient.

Born in Norway, Dr. Hovde studied medicine at the University of Oslo, and in 1889 came to the United States. He settled and practised in Vermilion and Sioux Falls, S. D. In 1900 he moved to Duluth, where he had been practising since.

For twelve years, until 1927, Dr. Hovde was a member of the St. Louis county poor commission, and took an active part in this work. He was also a member of the St. Luke's hospital staff and of the local and state medical organizations.

Surviving him are his wife; two daughters, Mrs. Arnold Berg, Duluth, and Miss Valborg Hovde, who teaches school at Hibbing, Minn.; one son, Dr. Rolfe Hovde, of Winthrop, Minn.; and grandchildren.

A. G. Moffatt

1865-1929

Dr. A. G. Moffatt, of Howard Lake, Minn., died at his home Dec. 18, 1929. Dr. Moffatt had practised in Howard Lake for 32 years. He was for several years president of the Wright County Medical Society, was a member of the State Medical Association and the board of medical examiners. During the world war he held the rank of captain and was stationed at Ford Sheridan.

Dr. Moffatt was 64 years old. He is survived by his widow; two daughters, Mrs. E. W. Ryley of Honolulu, and Mrs. W. T. Campbell of Minneapolis; and two sons, A. M. Moffatt of Chokio, and Dr. R. H. Moffatt of Morris, Minn.

TRUTH ABOUT MEDICINES

(Continued from Page 127)

Merthiolate—Sodium Ethylmercuri Thiosalicylate.—Merthiolate contains from 49.15 to 49.65 per cent of mercury in organic combination. Merthiolate is a potent germicide for spore-bearing and non-spore-bearing bacteria. It is used for sterilizing tissue surfaces. It does not precipitate with serum proteins. Merthiolate is much less toxic than mercuric chloride. Merthiolate is supplied in the form of merthiolate solution 1:1,000, containing 1 gram of merthiolate in 1,000 c.c. of water, buffered with 1.4 Gm. of sodium borate in 1,000 c.c. and containing sodium chloride to make the solution approximately isotonic. Eli Lilly & Co., Indianapolis. (Jour. A. M. A., December 7, 1928, p. 1809.)

Polyanaerobic Antitoxin.—An anaërobic antitoxin (New and Non-official Remedies, 1929, p. 346) prepared by immunizing horses with the toxins of *B. tetani, B. Welchii, Vibrion septique* and *B. oedematiens.* It is marketed in bottles containing 100 c.c., each 100 c.c. containing at least 5,000 units of tetanus antitoxin, 75 units of Welch bacillus antitoxin, and sufficient antitoxin to neutralize 50,000 minimum lethal doses of *Vibrion septique* toxin and 100,000 minimum lethal doses of *B. oedematiens* toxin. Cutter Laboratory, Berkeley, Calif.

Normal Horse Serum Without Preservative.—A normal horse serum (New and Non-official Remedies, 1929, p. 344) marketed in packages of one vial containing 100 c.c. H. K. Mulford Co., Philadelphia.

Sulpharsphenamine-De Pree, 0.9 Gm. Ampules.—Each ampule contains sulpharsphenamine-De Pree (New and Non-official Remedies, 1929, p. 71), 0.9 Gm. De Pree Chemical Co., Holland, Mich. (Jour. A. M. A., November 23, 1929, p. 1649.)

Thompson's Maltose and Dextrin.—A mixture containing maltose, 51 per cent; dextrins, 45 per cent; sodium chloride, 2 per cent; and moisture 2 per cent. On the claim that maltose is more readily assimilated than other forms of sugar, Thompson's maltose and dextrin is proposed to supplement the carbohydrate of cow's milk or of water modifications of cow's milk. Thompson's Malted Milk Co., Inc., Waukesha, Wis. (Jour. A. M. A., December 21, 1929, p. 1971.)

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of December 11, 1929

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, December 11, 1929. Dinner was served at 7 p. m. and the meeting was called to order at 8 p. m. by the President, Dr. C. N. McCloud. There were 49 members present.

Minutes of the November meeting were read and approved.

The Secretary read the Annual Secretary's and Treasurer's reports. A motion was carried that they be accepted. Dr. Drake included in his Secretary's report his resignation as Secretary-Treasurer. A motion was carried that a rising vote of thanks be given to Dr. Drake for his faithful and efficient service to the Academy.

Dr. Geo. D. Head read, for Dr. J. W. Bell, the following report of the Committee appointed to draw up a memorial to Dr. Louis A. Nippert, and a motion was carried that this be spread upon the minutes of the Academy and a copy sent to Dr. Nippert's family:

Louis Albert Nippert, 1860-1929. The Minnesota Academy of Medicine is again called upon to mourn the death of one of its oldest and most revered members, Louis Albert Nippert.

He was born in Basel, Switzerland, April 14, 1860. His father was a Methodist clergyman who at one time was President of the Methodist Theological Seminary at Frankfort-on-Main, Germany. His early education was carried on in the schools of Switzerland and preparatory to his college course he took work in the gymnasium and polytechnical high school at Karlsruhe, Germany. His parents later came to this country and located in Cincinnati, Ohio, where he completed his academic education.

Dr. Nippert began his professional studies in 1880 at Miami Medical College, Cincinnati, graduating in the class of 1883. After a year spent as an intern in the Cincinnati Hospital and a year as resident physician, he took post-graduate work in Paris and Vienna and then located in general practice in Minneapolis in April, 1885.

He was married in June, 1888, to Miss Mary Rauen. A daughter, Lillian, and a son, Rauen Louis, were born of this union, the son dying in 1909. Surviving him are his wife; his daughter, Mrs. E. F. Zelle; four brothers, Dr. Henry T. Nippert of St. Paul, Dr. Edgar Nippert of Los Angeles, Judge Alfred Nippert and Herman Nippert both of Cincinnati; and three sisters, two living in Cincinnati and one in Seattle.

Dr. Nippert died from a cranial fracture sustained while riding his horse, November 6, 1929.

Beginning his professional career as a general practitioner he developed those fine qualities of heart and mind born of the hard and trying experiences of a pioneer doctor. To a large clientele, many of his patients being poor or in moderate circumstances, he gave the best that was in him at all times without thought of his own comfort or health.

His later years were devoted to consultation practice in Internal Medicine. His large experience, analytical mind, splendid medical training, and cheering personalty admirably fitted him for this specialty. The outstanding qualities of his character were his loyalty to the high ideals of his profession and his faithfulness to duty. A number of times the profession had honored him without self-seeking on his part. He was elected President of this Academy in October, 1912, and took office in November, 1912. His Presidential Address was entitled "The Etiology, Diagnosis and Treatment of Acute Infections of the Pleura and Lungs." He was also elected to the presidency of the Hennepin County Medical Society.

He was appointed Instructor in Clinical Medicine in the Medical School of the University of Minnesota in 1898, and was made Professor of Clinical Medicine in 1902. Many of his old students, some of them members of the Academy, will remember the practical character of his instruction, well-grounded in a thorough knowledge of anatomy and pathology. He served the University and the state as a medical teacher until the reorganization of the faculty in 1913, at which time he resigned.

In 1907 Dr. Nippert again studied in Europe and spent much time in the hospitals and clinics.

He was a charter member of the Minnesota Society of Internal Medicine, and, in spite of the fact that a physical infirmity made it difficult for him to do so, he was always present at the all-day sessions of this Society.

The Staffs of Abbott Hospital and Hillcrest Hospital were honored by his name upon the list of their active membership.

The following is a bibliographic list of his contributions to medical literature:

Septic Endocarditis. Northwest Lancet, 1904, Vol. 24, p. 39.

General Considerations in the Treatment of the Earlier Stages of Pulmonary Tuberculosis. Northwest Lancet, 1905, Vol. 25, p. 183.

Diagnosis and Therapeutics of Pneumonia. Medical Brief, St. Louis, 1907, Vol. 35, p. 179.

Observations on the Methods of Diagnosis in some of the Clinics of Germany. Jour. Minn. Med. Assn., 1908, Vol. 28, p. 197.

The Diagnosis and Treatment of Incipient Tuberculosis. Jour. Minn. Med. Assn., 1908, Vol. 28, p. 508.

The Etiology, Diagnosis and Treatment of Acute Infections of the Pleura and Lungs. Journal-Lancet, 1913, Vol. 33, p. 249.

Prognosis and General Management of Pneumonias. Journal-Lancet, 1921, Vol. 41, p. 66.

The Committee: J. W. Bell
Geo. D. Head
S. Marx White.

The annual election was held at this meeting, and the counting of the ballots showed that the following

members were unanimously elected as officers for the year 1930:

President—Dr. Gustav Schwyzer (Minneapolis).

Vice-President—Dr. James S. Gilfillan (St. Paul).

Secretary-Treasurer—Dr. R. T. LaVake (Minneapolis).

Dr. J. M. Armstrong (St. Paul) showed several original first volumes of medical magazines published in the United States:

1. In 1797 the first scientific periodical publication and the first medical journal was published in North America. This is a copy of Volume I of that journal "The Medical Repository" published in New York (1797-1824). Volume I contains nothing of particular value to us at the present time and much of the material in it is not strictly medical. You may look it over and judge for yourselves. However, it must have filled "a long-felt want" as Volumes I and II were reprinted in 1802 and again in 1804. This particular volume I hand you is the 1804 reprint. Many interesting things might be said about its Editor but time does not permit.

2. This second volume is the first volume of "The Philadelphia Medical and Physical Journal" which was published from 1804 to 1809. There are one or two curious items in it. Whether it can be called the second medical journal published in the United States, I do not know, as the Philadelphia Medical Museum was published also in 1804 and ceased in 1811. I have no copy of this latter journal.

3. This third volume is the first volume of the "New England Journal of Medicine and Surgery" published in Boston in 1812. We are fortunate in having a full set of twenty-seven volumes in our Ramsey County Medical Library. If you will look over the table of contents you will find the names of many of the notable medical men of Boston among the contributors.

4. This fourth volume is Volume I of "The American Medical Recorder" published in Philadelphia in 1818. It continued publication until 1829. There are some quite interesting articles in this volume and also in the succeeding volumes but I cannot take the time to show the other volumes though we have a run of the first seven volumes.

5. This fifth volume is the first volume of "The Philadelphia Journal of the Medical and Physical Sciences" published in 1820, Nathaniel Chapman, editor. I call your attention to the title page where you will find printed the following quotation from the Edinburgh Review, No. LXV: "In the four quarters of the globe, who reads an American book or goes to an American Play? or looks at an American picture or statue? *What does the world yet owe to American Physicians or Surgeons?* (The italics are Chapman's, not Sidney Smith's.) Chapman was an Edinburgh graduate himself but was a thorough Philadelphian also and this statement was galling. He would start a medical journal and show the world the injustice of this statement. The journal continued under this name until 1827, when Isaac Hays, who had been assistant editor for a year, became editor. Hays thought the Journal should be more national in character and changed its name to "The American Journal of the Medical Sciences," under which name it is now conducted and well known to all of you as one of the foremost medical periodicals of the world. There is no doubt Chapman made good when he challenged Sidney Smith.

I might say that Sidney Smith was hardly correct, as Dorsey's Surgery was in 1818 reprinted in Edinburgh for use as a textbook in that University. John Syng Dorsey wrote the first American treatise on Surgery, published in 1813. I will show it to you some other time. Isaac Hays edited this great journal from 1826 to 1869 and after his death his son, I. Mimis Hays, was editor until 1901. Thus for 75 years it was "Hays' Journal" and so known to many of the past generation. With the exception of the Edinburgh Medical and Surgical Journal, the American Journal of the Medical Sciences is the oldest medical periodical in the world. The whole history of American Medicine and the progress of Medicine during its life may be found in its pages.

6. This collection of papers, while not strictly copies of a medical journal, are of intense interest and a literary curiosity, as the "Rush-Light" was published weekly in New York for the sole purpose of heaping abuse and ridicule on Dr. Benjamin Rush of Philadelphia. It was published by Wm. Cobbett, who wrote sharp articles under the name of Peter Porcupine. Cobbett was the proprietor of the "Porcupine Gazette" of Philadelphia, published as a Democratic organ under the patronage of Thomas Jefferson to discountenance the Federalist party, which was strong in Pennsylvania. Porcupine, in his abuse of Rush, went a step too far and, instead of confining his remarks to Rush's political activities, abused him as a physician. Rush sued Cobbett for libel. The suit being tried before a Court with Federalist leaning, a verdict of $5,000 was obtained —an enormous sum in those days. Cobbett fled to New York and retaliated by publishing the "Rush-Light." Five weekly numbers were gotten out. Early in 1800, when the Federalist party made it too hot for him even there, he went to London and printed two more copies. I show you the copies printed in New York and hope at some time to secure the remaining numbers. Cobbett readily obtained employment as a political pamphleteer in England and was later elected to Parliament. (See McMaster's History of the People of the United States, and the Encyclopedia Britannica, under Cobbett.)

Last year the Academy decided to award a medal at its annual meeting to the member making the most noteworthy contribution to its program during the year. The special Awarding Committee, consisting of Drs. Colvin, Gilfillan and Bouman, this year decided to award the medal to Dr. Arnold Schwyzer of St. Paul.

Dr. A. R. Colvin (presenting the medal for the Committee): Perhaps it is quite unnecessary, in presenting this medal to one whom you all know so well, to say more than that it gives us all great pleasure to present it. It may, however, be well to say that the

decision to award it to Dr. Arnold Schwyzer was enthusiastically unanimous as to the Committee and also as to the Academy.

In awarding this first medal for the most noteworthy and valuable contribution to the Academy for the past year, it is impressive that the recognition has been of the value of the presented experiences from the wide range of daily work of an earnest worker, combined with the interesting and constructive discussion of the work of others presented here. Experience looms large in medicine, and when experience comes from a broad, deep and original thoughtfulness and is presented with youthful enthusiasm, it is of utmost value to the Academy.

Allow me, Sir, to present with great pleasure the medal awarded by the Academy for the most noteworthy contribution during the past year.

The Committee: A. R. Colvin, Chairman.
Jas. S. Gilfillan
H. A. H. Bouman.

Dr. Arnold Schwyzer (accepting the Academy Medal): I surely feel that this is a very great honor, but I think the Committee might have chosen better when I look around and see the number of men who have made excellent contributions to this Academy. I assure you that I feel very very deeply when I express my appreciation of this testimonial. When an appreciation comes from the men with whom one works and meets all the time, I am sure it is worth more than when it comes from the outside. Though I can't quite see how I have earned it, I thank you heartily.

Dr. H. A. H. Bouman showed an enlarged drawing of the medal and gave the following interpretation:

White civilization while confined to Europe was in great danger a number of times of becoming overwhelmed by the Asiatics. The invasion of the Persians was one of the early historical occasions. The Greeks, under the leadership of Athens, defeated the enemy and dispelled all fear of future invasion. The will to live and to be free men had been hammered out during the years of bitter warfare and a national accomplishment of the first magnitude was theirs. Gratitude and exaltation forced expression; they built the Parthenon on the Acropolis in the sight of all to honor Minerva, their beloved Pallas Athene. The incomparable period of Pericles, which stocked the East and the West with pioneers and leaders, must honor Minerva. Menos, the indomitable mind, striving for the best things in man, his art; the deified personification of this mindedness can be seen in plastic form on the face of this medal. The bust of a marvelous woman; she was not born like others, but sprang from the lofty forehead of Zeus. The head of Gorgo indicates her father's Aegis—the wonderful shield. The visor is tilted back. In peace or war that wondrous human face radiates serene composure and patience, dignity and determination and persistent energy.

All those who brought forth their talents to be used and amplified looked upon her as their patroness; she was the illusiveness of their lives and their realizations. The spirit, that persists to do and accomplish, ruled them whom we call the Salt of the Earth in our day.

Dr. Harold Hullsiek (St. Paul) read his Thesis, entitled "Adenomatous Polyps of the Sigmoid and Rectum"; this was illustrated with numerous lantern slides.

DISCUSSION

Dr. Donald Balfour (Rochester): I enjoyed very much hearing this thesis. Dr. Hullsiek has referred to one very important fact of which we should often be reminded; that is, the necessity for routine rectal examination in all patients. In spite of this being a platitude, one still finds many patients with a lesion of the rectum, sigmoid and colon, associated with bleeding, and who have had, in the immediate past, an operation for hemorrhoids to relieve them.

Dr. Theodor Bratrud (Warren, Minn.): The subject of Dr. Hullsiek's interesting paper interests me particularly with reference to the diagnosis of "intussusception."

I reported in 1914 the case of a 16-year old girl who came to us in 1913. She gave a history of several attacks of vomiting and was vomiting when brought in. We gave her an enema and she had a profuse foul stool. After this, a mass could be felt above the left Poupart's ligament. She started vomiting again and we found an intussusception. We could palpate two small tumors in the sigmoid. These were excised. The stump bled quite freely, so it was whipped over with catgut. The tumors were a little larger in size than a walnut.

She did well until the 14th day postoperative—when she was going to go home, but started vomiting again. This time we found an intussusception on the right side. On opening the abdomen we found that she had an intussusception of the ileum, cecum and ascending colon. We could palpate several more masses in the lower ileum which, on opening the ileum, showed us a group of tumors similar to those in the sigmoid. At that time, we made a general exploration of the abdomen and found a mass higher up to the left of the midline about the size and consistency of a banana. On delivering this mass, we found an intussusception and in this area we found several more tumors similar to those in the sigmoid, which were excised.

After the second operation she was well for about five years, when she was brought to the hospital in a moribund condition. The postmortem showed the lower ileum, cecum and colon intussuscepted almost down to the anus and the bowel was filled with numerous adenomatous polypoid masses.

A year later a 4-year old boy was brought in with a diagnosis of appendicitis. We found an intussusception of the lower ileum, cecum and ascending colon which we could not reduce. A resection with end-to-side anastomosis was done. In the resected piece of bowel we found multiple tumors which were more polypoid in structure than adenomatous. To date, this boy has been well.

We had a case this year of a 70-year old man, very anemic, who had been bleeding for about a year. We found seven polyps in the sigmoid, which were removed by high frequency current. The bleeding stopped and he improved for two or three months but now has

masses in the liver, a great deal of pain in the spine and is going down hill very rapidly.

Dr. L. C. Bacon (St. Paul): It is sometimes interesting to know what nature does with these rectal growths. This excellent paper recalls to my mind a case I saw many years ago. A child 6 years of age had a rectal polypus within reach of the finger. The family refused operation though repeatedly urged to consent. I had an opportunity to follow that case to termination. The pedicle gradually elongated over a period of 6 or 8 months and eventually there was no polypus there. Nutrition must have been cut off through traction upon or twisting of the pedicle and separation occurred.

That case has made me feel that in children, especially in outlying districts, nature certainly does take care of some of them. I am not advocating leaving these cases—not by any means.

Dr. H. T. Nippert (St. Paul): I attended a meeting of the Tri-State several years ago and some man made the statement at one of the sessions, "Don't be afraid to put your finger in the rectum, otherwise you might get your foot in it."

Dr. Hullsiek thanked the members of the Academy for their discussion of his paper.

Dr. F. E. B. Foley (St. Paul) gave a report of "An Unusual Case of Extra-Vesicle Urinary Drainage" and showed several lantern slides. He also discussed the embryology and development of these anomalies of the urinary tract.

DISCUSSION

Dr. Arnold Schwyzer (St. Paul): We owe thanks to Dr. Foley for his splendid presentation of this subject. In listening to him, one cannot help but be impressed by the fact that the more we know the fine points in these anomalies, the more we can find conservative measures. I have heard tonight expressed the respect for the renal parenchyma, and I think that is a very important point. The saving of the parenchyma, if there is a possibility to readjust things, is very important, especially in women with possible pregnancies which may make great demands on the kidney substance.

The variety of anomalies shown here is very interesting and instructive. To emphasize the preservation of what can be saved, let me mention a case I saw yesterday. It is a woman on whom I had done a heminephrectomy, or rather a resection of one-third of the kidney, seventeen and a half years ago. The young woman was brought into the hospital after four weeks' illness. During the last week she had severe chills every day and high temperatures, some pain in the right kidney region, with some albumin and cloudy urine. At operation we found the upper third of the kidney riddled with abscesses. We incised through that upper pole and a little beyond. These abscesses were spread all through the thickness of the parenchyma, but stopped abruptly in a straight line toward the remainder of the kidney. The removal of that upper third of the kidney, with the preservation of the other two-thirds, allowed this woman to face the future with two kidneys. She has since married and has gone through pregnancy without trouble. The result in that case was very gratifying. The patient has had no trouble from that kidney.

In a case of double renal pelvis with hydronephrosis in the upper one, we made an anastomosis between the upper hydronephrotic and the lower normal pelvis. This also gave quite a satisfactory result. The operation was over eight years ago, and the patient is in good shape. This was a pyelo-pyelostomy.

The meeting adjourned.

R. T. LaVake, M.D.
Secretary.

PROGRESS

Abstracts to be submitted to Section Supervisors.

Members are urged to abstract valuable articles which they run across in their reading and send the abstracts to the physicians in charge of the respective sections. In order to avoid duplication it would be well to communicate with one of the section supervisors before the article is abstracted.

MULTIPLE INTERCOSTAL NEURECTOMY FOR PULMONARY TUBERCULOSIS: John Alexander (Amer. Rev. Tuberc., 1929, XX, 637). The author resected the phrenic and intercostal nerves on one side of a dog and obtained almost total immobility of that side of the chest as well as a marked falling in of the ribs overlying the lung. Since then he has performed this operation on six patients who were considered too poor a surgical risk for the more drastic procedure of thoracoplasty. Resection of the second to eleventh intercostal nerves together with homolateral phrenic exeresis puts that side almost completely at rest during quiet respiration, due to paralysis of all muscles involved in quiet respiration and in addition some of the accessory muscles used in forced respiration. The remaining unparalyzed accessory muscles function in the necessary cough reflexes and raising of accumulated pulmonary secretion.

Indications for intercostal neurectomy are similar to those for artificial pneumothorax, thoracoplasty and phrenectomy.

The lesion must be predominantly unilateral and artificial pneumothorax or phrenicectomy or both

together should have been given a fair trial and found insufficient due to adhesions. Intercostal neurectomy is the choice in preference to thoracoplasty in patients with poor general cardia-circulatory condition, or too great age to justify even a primary stage thoracoplasty. The chief contraindication is a large amount of sputum (100 c.c. per day) that the patient might be unable to raise because of impairment, by the operation, of the power to expectorate.

The technic of the operation consists mainly in making an incision over the angles of the ribs from the second to the eleventh rib. The intercostal muscles are then incised midway between the ribs, the incision centered at the angles of the ribs, two to three centimeters of each intercostal nerve is resected from the second to the eleventh inclusive, care being taken not to damage the posterior rami that supply the sacro-spinal muscles.

Intercostal neurectomy is not intended as a substitute for thoracoplasty. The former may be used in the cases not suitable for thoracoplasty. Such patients include both those who are too ill for thoracoplasty and those that are not ill enough, and yet for whom further aid is necessary in order to bring about arrest of the disease.

E. F. Allison, M. D.

PLACE OF THE HOSPITAL IN THE PROMOTION OF PUBLIC HEALTH PROGRAMS: Matthias Nicoll, Jr., M.D. (Hospital Social Service, 1929, XX, 456). The hospital must be counted as an integral part of any health program. A tuberculosis sanatorium should be the center of anti-tuberculosis work, especially throughout the rural districts; the superintendent should be on a full time basis and should be a technical adviser on tuberculosis with administrative and teaching capacity to insure the confidence not only of patients but of the local medical profession.

The problem of the care of the insane and mentally defective can only be solved by adequate appropriations for special hospitals.

As recently pointed out by Professor James Ewing, the provision of facilities for diagnosis and treatment of early cancer is a public responsibility which cannot be escaped.

There is a great scarcity of institutions to which post-operative orthopedic cases and others handicapped by disease and accident may be sent for rehabilitation so that they may become self supporting. Such institutions should provide training for orthopedic nurses.

The hospitalization of maternity cases seems logical but a careful study of the equipment and methods of obstetrical service in such hospitals is the duty and responsibility of the organized medical profession at the present time.

The provision of hospital facilities in the rural districts, of community hospitals, properly planned and operated, seems to be a recognized means of securing the retention of capable physicians in such localities, and so securing not only adequate medical attention in both the homes and the hospital. When well established, such hospitals will serve as centers for State and local health services, such as public health nursing, prevention of diphtheria, prenatal care, child welfare clinics, and, in the absence of a local tuberculosis hospital, tuberculosis clinics. It may well be the meeting place also for conference between health officials, state and local, and the general medical profession.

DONALD K. BACON,
LOWRY BLDG., ST. PAUL
VERNE C. HUNT,
MAYO CLINIC, ROCHESTER

OVARIAN TRANSPLANTATION: Chas. C. Norris and Charles A. Behney, Philadelphia (Surg., Gynec. & Obstet., Vol. XLIX, No. 1929, No. 5, 642). What the reaction of the patient to surgical menopause will be is best predetermined by the temperament. The nervous, highly developed, neurotic married individual is prone to suffer most. In selected cases, therefore, where conservation of the ovary has been impossible, ovarian transplants or grafts are desirable.

The series reported consists of patients in the child bearing age and in whom only autotransplantation was done. Practically all were suffering from pelvic inflammatory disease in the chronic stage. The Blair-Bell technic was closely followed in the earlier cases. In later cases the ovary after decapsulation was divided in two, three or four portions and transplanted in separate pockets in the rectus muscle. This method results in better blood supply to each part and higher percentage of "takes." Small grafts not more than eight millimeters in diameter and considerably less in thickness have been most satisfactory.

Advantages in this type of graft are:

1. Complications rarely develop.
2. Should complications occur they are easily handled, being extraperitoneal.
3. Grafts usually "take."
4. The sudden development of the menopause is generally averted, and when it occurs is more analogous to the normal than if the grafting had not been performed.

The life of the transplanted ovary is probably not more than two or three years. The grafts may become tender for a day or two each month but rarely give serious trouble.

C. W. Mayo, Jr.

ACUTE EDEMA OF THE PANCREAS: Edward Archibald (Ann. Surg., 1929, XC, 803-816). By the transduodenal injection of non-infected bile directly into the pancreatic duct the author has repeatedly produced changes in the pancreas of animals which both grossly and microscopically appear to represent acute edema without necrosis. The effect appeared identical when either gall bladder bile or hepatic duct bile was employed. The beginning of this change could be observed grossly within half a minute after the injection. After the elapse of five minutes the major portion of the pancreas had become involved. Care was taken not to inject the bile under pressure. Operation upon the same animals several days later revealed almost complete subsidence of the process both grossly and microscopically. The similar use of infected bile caused the graver lesion of necrosis.

Archibald feels that a condition may exist in the human similar to that which he has been able to produce in animals by the injection of non-infected bile into the pancreatic duct. In substantiation of this persuasion he reminds the reader that not infrequently patients who have had an interval exploration because of a history of repeated short abdominal colics have been found to have a negative abdomen at operation. The inference that the pathologic process had subsided during the interval he thinks quite logical. He further cites a case of his own in which he operated before complete regression of the acute attack had occurred. At operation palpation disclosed definite enlargement of the pancreas, but he was unable to visualize the organ. As further evidence that such a condition may exist he reviews the work of Zoepffel, who in 1922 described acute edema of the pancreas found at operation during the acute stage of the common variety of gall bladder colic.

The symptoms suggesting such a condition consist of severe pain located in the epigastrium with radiation to the left abdomen and left back, associated with localized tenderness over the pancreas and a corresponding area of skin hyperesthesia.

The author feels that all patients having symptoms suggesting such a diagnosis should undergo exploration because of the inability to determine which cases may, if operation be postponed, be found to have acute pancreatic necrosis. The principle of the operative procedure he thinks should be that of bile drainage for one to two months in order to eliminate further similar attacks. He recommends cholecystostomy and removal of stones if present; if cholecystectomy has already been performed, choledochostomy.

EYE, EAR, NOSE AND THROAT

SUPERVISORS:
VIRGIL J. SCHWARTZ,
MEDICAL ARTS BLDG., MINNEAPOLIS
ARTHUR C. DEAN
HOT SPRINGS, SOUTH DAKOTA

STENOSIS OF THE NASOPHARYNX: F. A. Figi, M.D., Rochester, Minnesota, Arch. of Otolaryng., Nov., 1929, 10, 5, 480). Stenosis of the nasopharynx is usually acquired, but there are a few cases of true congenital stenosis in the literature. In the cases of acquired stenosis, syphilis is generally considered to be the most common cause. The next most common causes are trauma, diphtheria, tuberculosis, congenital anomalies and inflammatory lesions.

In the cases seen at the Mayo Clinic the most common cause was trauma incident to the removal of tonsils and adenoids. The interval between the time of operation and the onset of symptoms varied from a few weeks to two years. In about 40 per cent the trouble developed during the first decade of life and in more than 50 per cent the onset was before the age of 20.

The nasopharyngeal stenosis seen in cases of scleroma is always concentric and appears to be due as much to infiltration and thickening of the wall of the nasopharynx as to cicatricial contraction. The symptoms are dependent on the degree of obstruction. The patient often accustoms himself to breathing through a very small opening and may present few or no symptoms. With almost complete atresia the symptoms are those of nasal obstruction. Mucous membrane changes, sinus infection and deafness ensue. Anosmia may be present. Vocal resonance may be changed. Chronic inflammation of the pharynx may also be present.

Many and varied procedures have been advocated and tried for relief of this condition. The simplest and most successful procedure is that presented by Nichols. He inserted a silk suture through the small nasopharyngeal opening well into the lateral extent of the region of scarring. This suture was tied and left in place till a cicatrized tract developed. The posterior border was then freed from its attachment to the pharyngeal wall out to this point.

There has been a great change in the prognosis given patients with this condition in the past few years. The reports of Nichols and Mackenty are very optimistic. A favorable prognosis is given as a routine provided the patient is able to remain under observation for a sufficient length of time, varying from 3 to 8 months.

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

THE CONQUEST OF CANCER BY RADIUM AND OTHER METHODS. Daniel Thomas Quigley, M.D. Philadelphia: F. A. Davis & Co., 1929. 539 pages. $6.00.

This is a well printed volume of 539 pages, containing numerous illustrations. Section IV contains extensive data on diseases other than cancer in which radium has proved of value. One almost wonders at times if this book was intended for the layman, since it largely lacks a scientific nomenclature and accuracy as well as methods of technic. For example, we are informed, "Cancer, instead of being a complex thing of which we know nothing, is a very simple thing of which we know a great deal. We probably know more about cancer than about any other chronic disease. The basic fact in connection with new growth of tumors, then, is irritation of living cells by micro-organisms and their toxins. No one micro-organism is known to have such a widespread distribution."

One meets frequently the terms "roots of the cancer," "baby cells," and on page 160 we are informed melanoma growing in the eye may arise from the retina. On page 158 the author speaks of glioma of the eye in the adult.

This writer has tremendous enthusiasm, reporting wonderful results, but he fails to indicate how he obtained these results. We can only wish he had given us a definite technic as to how such results are obtained. Every radium worker welcomes information on this point.

Agreement is accorded his statement that the general practitioner has little conception of the physical properties of this very potent agent he is using and that radium service should be centered in well equipped radium hospitals with a trained personnel.

L. A. Lane, M.D.

A STUDY OF MASTURBATION AND THE PSYCHOSEXUAL LIFE. John F. W. Meagher. Second edition. 130 pages. Cloth, $2.00. New York: Wm. Wood and Co., 1929.

This book presents a thorough study of the subject of masturbation. The importance of the well accepted principle that sex information must begin early in life is stressed, the best guide being the child's own questions. This essay helps to instill the proper insight into the psychosexual life of the child and adolescent that is vital to the proper attitude of the physician. A discussion of the auto-erotic, homosexual and heterosexual trends of the individual lays the proper foundation for the author's chief purpose. He finds masturbation an almost normal phenomenon for the child and adolescent, but not for the adult. The causes, symptoms, sequelæ and treatment of this habit are carefully reviewed. His conclusion that we are dealing with a psychopathological problem, requiring sympathy and understanding rather than medicine or surgery, is in line with the best modern medical thought.

This is a valuable book for anyone interested in the psychology of adolescence. It should be read by parents, clergymen and doctors, especially pediatricians interested in mental hygiene.

THE REPAIR OF FRACTURES*

CLAY RAY MURRAY, M.D.

Assistant Professor of Surgery, College of Physicians and Surgeons, Columbia University; Associate Attending Surgeon, Presbyterian Hospital in the City of New York

New York City

THIS is a subject of paramount importance to those engaged in the care of fracture cases. Some of the things I have to say will have a very familiar ring—you will find them in every textbook. Other remarks of mine, representing results of my own as yet unpublished investigations, as well as the published investigations of others working in the same or allied fields, will present a queer and interesting mixture of observed facts and attempts to explain them which seems to upset all our earlier conceptions as to the way in which bone tissue heals. Nor are we able, as a result of these newer observations, to replace our old ideas with any definite knowledge of how bone is actually formed in the healing process.

It seems, at first blush, unreasonable to present such a story to practising physicians—a destructive criticism of our present ideas, with no definite alternative to take their place. But the newer observations and the ideas which they have engendered afford us a fresh viewpoint which is of tremendous practical importance in the treatment of fractures. There is a current saying that it all depends on where you sit as to just what the picture looks like. And, as we have had to change our seats, so the picture has changed. We can begin now to understand why so many practical measures, which we have heretofore employed purely empirically, are successful, and therefore we are able to apply these measures more intelligently. We are able also to guard against, and to treat more intelligently and successfully, those conditions which we are accustomed to call delayed union and non-union. After all, it is the practical application in treatment of the ideas gained by modern research along these lines, and not the didactic discussion of them, that is important to men who are interested in the actual care of fractured bones.

All that follows deals with conditions in the adult only. The cell characteristics of the child may well be an entirely different story—there is much evidence that this is so—just as the clinical picture in children is so different from that in adults.

Let us first take up what we actually know about fracture healing. The picture of the gross in terms of visible callus or bone has not been materially improved upon since the description by Dupuytren in his Lecons Orales.[1] The whole story occupies six to twelve months, as illustrated in Figures 1 to 4.

Figure 1 represents the early provisional callus, which appears in two to four weeks. As one can see, it is similar in appearance to the plumber's wiping of a joint. It is usually fairly firm, but will slowly yield under pressure or continued stress of any considerable degree. The *x*-ray visibility is dependent on the amount of calcium present in terms of density of distribution. This may vary considerably, as may also the total amount of this callus, being least in greenstick and subperiosteal fractures and most in those with periosteum torn and with comminution of bone.

Figure 2 represents the gross picture of healing at eight to twelve weeks. The outside callus has been reinforced by a plug of callus joining the medullary canals of both fragments. There is as yet no bony union between the cortices of the two fragments. In the upper extremity this usually provides union sufficiently firm for full function without danger. In the lower extremity, because of the added function of weight bearing, it may not be sufficiently strong for full function, depending upon the weight of the indi-

*From the Department of Surgery, College of Physicians and Surgeons, Columbia University, New York. Read before the Great Northern Railway Surgeons Association, at Seattle, Washington, July 5, 1929.

vidual, the calcium density of the callus, the location of the fracture from the viewpoint of weight-bearing mechanics, etc.

Figure 3 shows the condition present at the end of four to six months. The outside callus has diminished

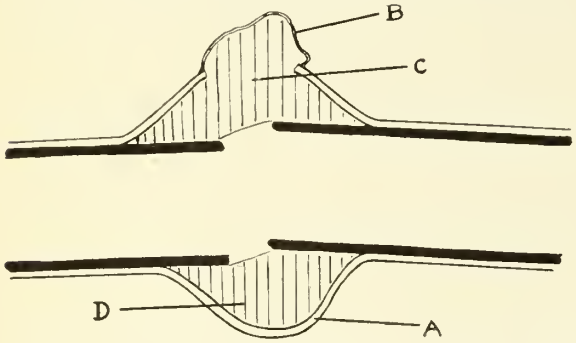

Fig. 1. *A.* Stripped-up periosteum. *B.* Torn periosteum. *C.* Callus. *D.* Callus.

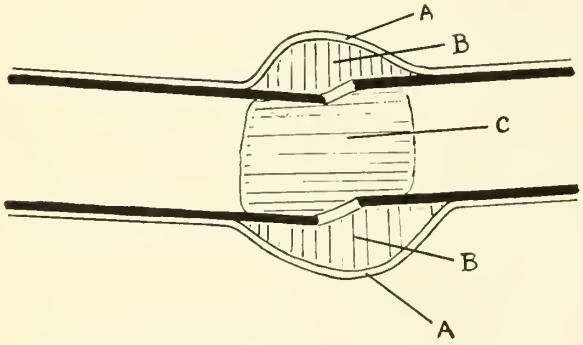

Fig. 2. *A.* Periosteum. *B.* Outside callus. *C.* Medullary callus.

in size and increased in density; the medullary canal shows a bony plug with visible vascular channels, and the cortices of the two fragments are joined by a bony callus. This is so-called solid bony union. Subsequent changes deal only with the architecture of the bone. That architecture is supposed to be in accordance with the stress and strain to which the bone is subjected—the so-called Wolff's law. As Carey[2] has shown, the factors involved may be many and varied. If subjected to the stress and strain normal for the bone involved, the normal architecture will be regained. If not, an architecture will be attained which is in accordance with the modified stress and strain placed upon the bone. This is not of necessity a mysterious or complicated process. A steel girder or column subjected to a given stress and strain will arrange its lines of crystallization in accordance therewith, and if the stress and strain be changed for a sufficiently long time it will rearray those lines to meet the new conditions. It is to bring about this resumption of normal architecture that fractured necks of the femur, after healing has taken place, are put on partial weight bearing, protected against compression of the callus and resultant angulation and coxa vara deformity by a walking caliper for some months. We know from experience that the homogeneous callus at this crucial point as regards weight-bearing is frequently unable to bear the burden until the lines of force transmission in the neck of the femur are at least partially restored by the action of Wolff's law.

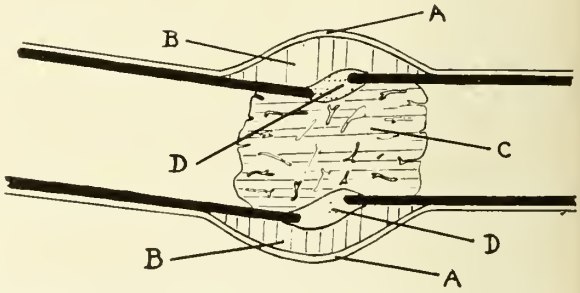

Fig. 3. *A.* Periosteum. *B.* Outside callus. *C.* Medullary callus. *D.* Cortical callus.

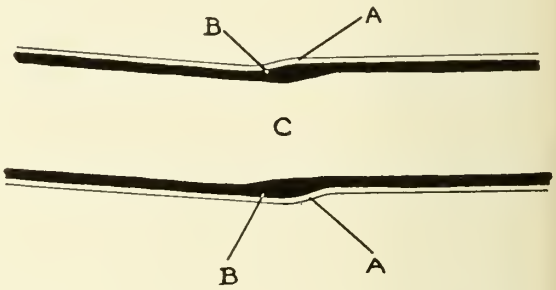

Fig. 4. *A.* Periosteum. *B.* Cortex. *C.* Medulla.

Figure 4 represents the final result nine to twelve months after fracture. The bone is healed and has regained its normal architecture, completing the picture in the gross.

Let us now turn our attention to the study by the microscope of what actually occurs in bone healing. On this score the newer observations have revealed facts which can be demonstrated in the illustrations which follow. These facts have changed completely our conception of how bony injury heals, and have done much to undermine our ideas as to how bone replaces the mere healing to give solid bony union.

The illustrations comprising Figures 5 to 22 are taken partly from articles published by Bancroft* [3,4,5,6], partly from his own private collection and partly from the files of the Department of Surgery, Columbia University. The observations recorded and the conclusions drawn are partly Bancroft's own as published, and partly mine as made in a further study of his work in conjunction with my own experimental study of fracture repair as cited below.[7] (The originals of the illustra-

*I am indebted to Dr. Bancroft for his courtesy in allowing the use here of his illustration. It is a pleasure to acknowledge my indebtedness to him not only for the illustrations and his own observations, but for the stimulus derived from his work to further study of the question.

tions were previously published in the following periodicals: No. 18, Am. Jour. Med. Sci.; Nos. 7, 9, 19, Arch. Surg.; No. 8, Ann. Surg. and New York State Jour.)

Figure 5 is diagrammatic of the details of the gross

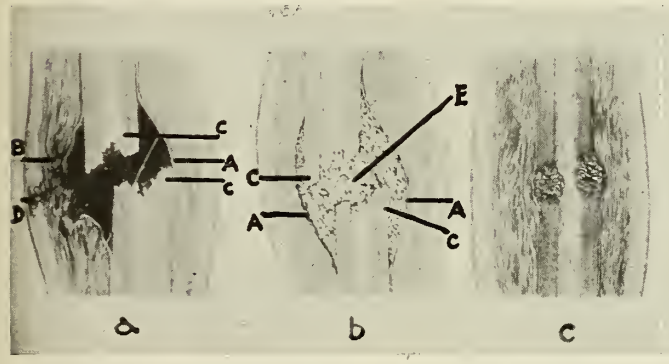

Fig. 5. *A.* Periosteum, real or apparent. *B.* Torn and infiltrated muscle. *C.* Broken bone ends. *D.* Infiltrated subcutaneous tissue. *E.* Callus.

shown in Figures 1 to 4. "a" represents the pathology at the time of fracture. It shows the broken ends of the bone (C), which we shall show later undergo death and autolysis to a variable degree. The periosteum is represented as intact on one side (A) and torn on the other. It is obvious that all granulation tissue on the sound side will of necessity be derived from the only soft parts available, which are the under surface of the periosteum, the so-called endosteum of the broken edges of the bone and the marrow tissue of the fragments. On the torn side it is equally obvious that the torn and lacerated muscle and fascial planes are allowed access to the fracture site, and granulation tissue produced in them can grow in to the site of the fracture. The extent and location of the hemorrhage and exudation at the fracture site is also worthy of note because of its distribution and the fact that the swelling produced causes a variable amount of circulatory and lymphatic disturbance (B) (D). These factors will all be dealt with later as to their influence on the course of the healing process. "b" represents the callus healing stage. The periosteum will be noted as apparently restored where it was torn before. As we shall show later, with tearing as extensive as here shown, the restoration of periosteal integrity is apparent and not real, the bridging tissue being derived from connective tissues outside the periosteum, viz:, muscle and fascial planes. The only morphological difference observable is the absence of the very vascular inner layer present in normal periosteum. Despite its source and this morphological difference, the new tissue functions effectively, and, so far as we can tell, in a normal manner as periosteum. This detail will be referred to again in its bearing on the question of the specificity of the periosteum as a tissue. The bony callus represented in this diagram shows numerous vascular channels, which we will show later to be at right angles to the long axis of the bone and to be the vessels of granulation tissue derived from outside the bone, in part at least. The question of the origin of the calcium deposited in that tissue to form bone will also be a matter for clarification. "c" represents the healed state with restoration of the bone architecture.

Figure 6 is diagrammatic of a late stage of callus repair and is a little more detailed representation of "b" in the preceding figure. Its captions explain it and it holds the same points of interest as were detailed in Figure 5 "b."

Figure 7 is a microphotograph of the healing of a comminuted fracture. In it can be noted the numerous fragments with microscopical evidence of death, as shown by lack of nuclear staining, and death of the ends of the cortical bone on either side of the region of comminution, with new bone production taking place about these areas of bone death. The direction of the vessels in many of these areas agrees very accurately with the diagrammatic representation in Figure 6, and the point brings up similar questions as to the source of the tissue of origin and of the calcium involved. The formation of the pseudoperiosteum and the absence of the deep vascular layer in it is also shown. The fact that the new bone formation occurs primarily about areas of microscopically dead bone is also a fact to be kept in mind.

Figure 8 represents a late stage of experimental comminuted fracture. The experimental technic was that of Bancroft in the study of repair of bone defects by the use of chip grafts. About one inch of a dog's radius was excised with its periosteum. The ulna was left intact to maintain the gap. The excised portion was scraped free of periosteum and fragmented and the small fragments were freed from so-called endosteum in so far as possible by scraping and then dropped back into the gap and the muscles sutured lightly to hold them in place. While devised for the study of chip transplants, the procedure reproduced realistically the condition of comminuted fracture with the fragments separated from the periosteum and with wide tearing of the latter. Studying the microphotograph from the viewpoint of a comminuted fracture of this type of 141 days duration, we see at A the broken

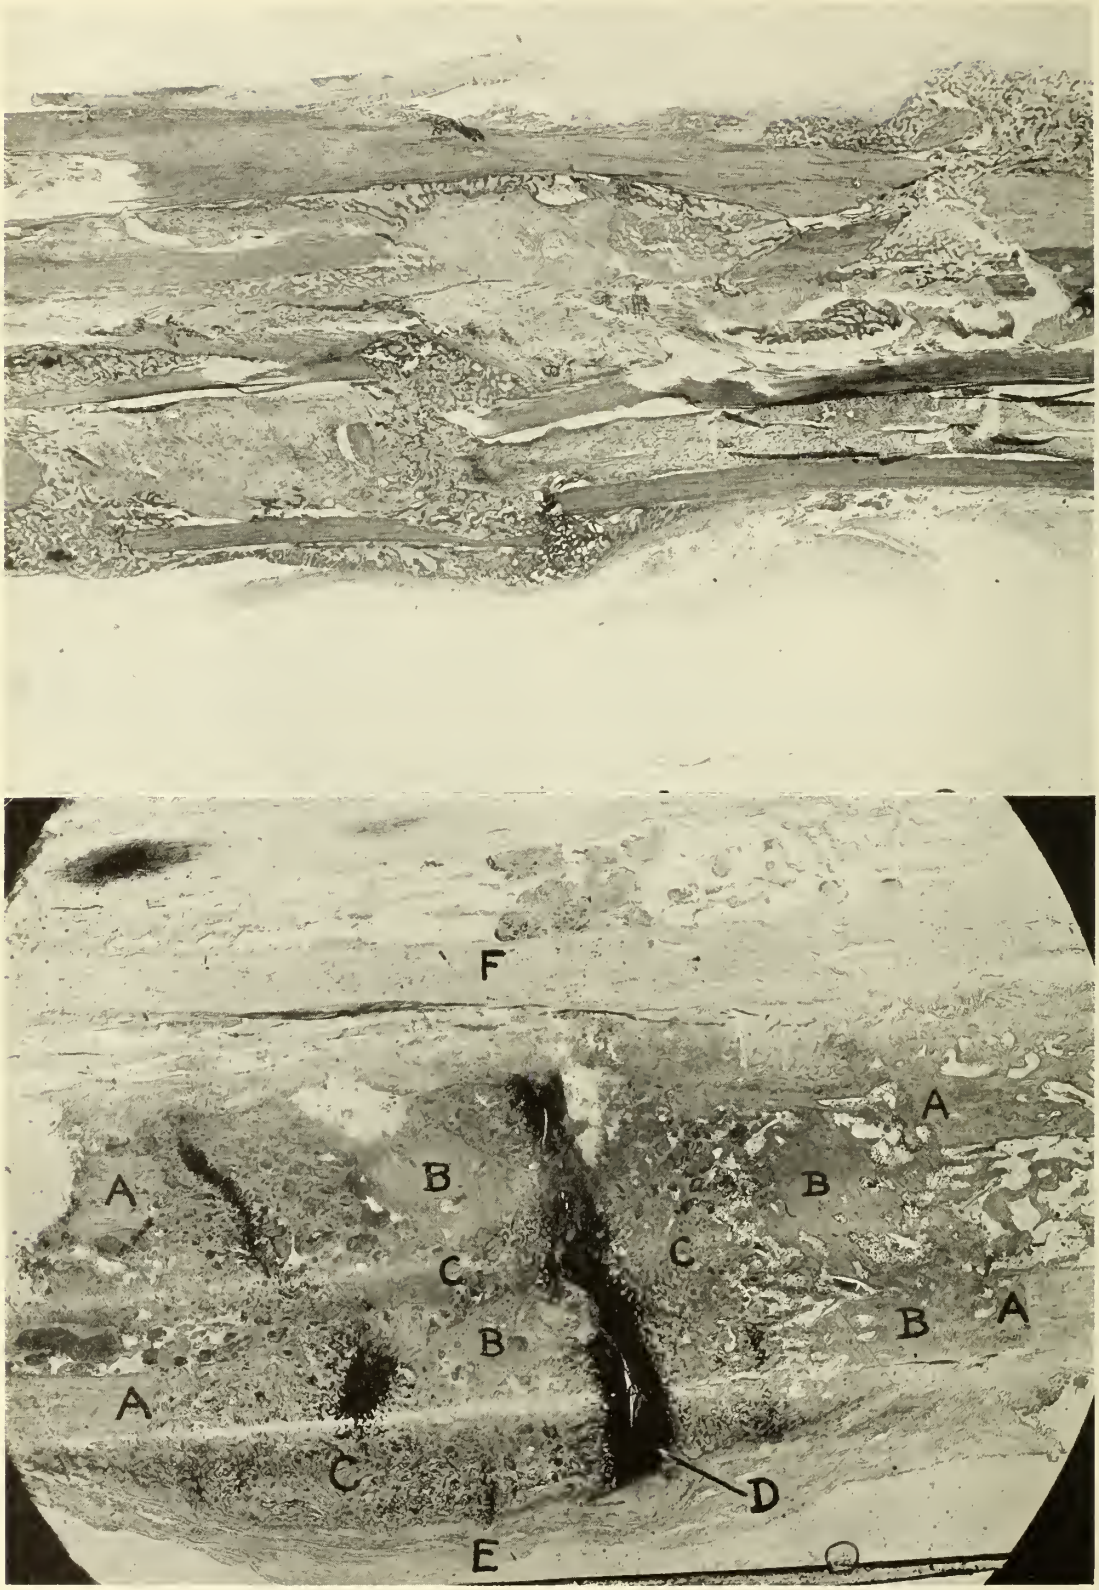

Fig. 7 (*above*). Healing comminuted fracture.

Fig. 8 (*below*). *A.* Broken bone ends (radius). *B.* Fragments. *C.* New Bone. *D.* Cartilage. *E.* Pseudoperiosteum. *F.* Ulna (intact)

bone ends with the comminuted fragments B lying between them, both showing microscopic evidence of death. The whole is amalgamated by a variegated structure comprising new bone, cartilage and connective tissue extending laterally on both sides beyond the bone limits for a considerable distance. We see that the new bone formation is to be observed principally about the bone fragments and the broken ends of the bone. We note that for a short distance from each broken bone end the direction of the vessels is in the long axis of the bone, but that in the intervening area, comprising four-fifths of the original gap in the bone, the vessels are at right angles to the long axis of the bone. In earlier sections these vessels are shown to be continuous with and apparently a part of the granulation tissue proceeding from the soft parts. These facts are of significance in regard to the question of the tissue of origin of the healing process, the source of the calcium utilized to transform that tissue into bone and the rationale of that transformation. We see also the formation of a pseudoperiosteum by the surrounding soft parts as in previous figures. We note also the diverse types of tissue present—cartilage, connective tissue and new bone—a matter into which we must inquire more deeply as we go on.

Figure 9 represents a low power microscopic picture (x 150) of one of the included fragments shown in Figure 8. The areas of obviously dead bone are denoted by the absence of nuclear staining, although the cell spaces are plainly apparent. One notes also that the vessels are apparently viable, as shown by normal nuclear staining of the vessel wall. Are these vessels the original ones of the bone fragment "revivified" by a new nutritional supply, or are they new vessels? Study of similar sections from a few days onward to the stage here shown makes it apparent that these vessels are new; that they are the vascular buds of granulation tissue invading the chips of hard bone by the only available channels—the pathways of the old vessels—just as they invade the fibrin network at the site of fracture. These vascular buds consist of the capillaries surrounded by a thin layer of accompanying fibroblastic cells. In the new channels which they occupy, one notes that live "bone cells" seem to exist in three or four layers in the cell spaces in the immediate region of the vessel and nowhere else. Are these "revivified" bone cells brought to life by the reëstablishment of circulation? If the site of this picture were out in the healing soft parts we should state immediately that they were the fibroblastic cells surrounding the capillaries to make so-called granulation tissue. And that is all they are here, invading in their progressive growth the only available space—the empty cell spaces in immediate proximity to the vessels which they accompany. And they are bone cells only as regards the fact that they occupy the cell spaces in the bone. Morphologically and by staining reaction they are not to be distinguished from fibroblasts.

Figure 10 is a higher power (x 375) of a small section of the picture shown in Figure 9, and brings out all the details more clearly. The morphological appearance of the cells, their distribution and the presence of empty cell spaces in the avascular areas are readily noted in this microphotograph.

Figure 11 represents a section taken through the site of a linear fracture in a dog which was given immediate treatment. The section was made after two weeks, at which time gross healing was apparently accomplished. At (B) will be noted the end of one bone fragment with absence of nuclear staining and empty cell spaces. This is "dead bone," comparable to the state of the bone chips in previous illustrations. At (E) there is to be seen "cyst" formation in the bone fragment end—an evidence of bone atrophy or the demineralization process. This is important. Some bone is killed by the trauma and by the vascular disturbance attendant upon it, and that dead bone is demineralized. This is comparable to the autolysis of any dead tissue through the action of ferments freed or activated by tissue death. What is important is the question as to what happens to the calcium freed by the demineralization of the bone and as to the form in which it exists. Circulation in this injured area is sluggish and slow, due to mechanical as well as inflammatory factors. This must be kept in mind. We do not know the form in which calcium exists in the bone or in the blood or tissue fluids. At (D) will be observed normal bone. (C) designates the callus lying between the bone ends. The apparent direction of growth is not from bone end to bone end, but is across the gap, perpendicular to the long axis of the bone fragments. This, as we have noted, is the direction of growth of the granulation tissue which later becomes bone in the experimental comminuted fractures cited above. (A) represents an area of cartilage present in the callus, although no preexisting cartilage can be premised, except on the basis of cell rests of embryonal origin. In this cartilage area the cell types range from frank cartilage cells to cells indistinguishable from the fibroblastic type, and the ground substance varies from the typical blue staining hyaline substance to that which is indistinguishable from the adjacent collagen fibers of ordinary connective tissue.

Figure 12 is a microphotograph of a three-day human callus recovered at operation. It is of extreme interest in that it shows typical new bone formation at this early stage in new connective tissue. In the upper right hand and lower left hand corners we can see fairly dense areolar tissue. The center of the picture is occupied by a loose meshed tissue in which calcium has been deposited to form a lace-like structure of new bone. The cells lying in this mesh of calcium are identical morphologically with the fibroblasts lying in the tissue outside. The calcium matrix merges into the basement substance of the areolar tissue at points so imperceptibly that it is extremely difficult to tell just where calcium deposition begins. In the lower right hand portion the typical appearance of new forming bone is present with linked, roughly ring-like areas of calcium surrounding small areas of areolar tissue; in the latter the capillaries are present. This will be shown in detail in later illustrations.

Figure 13 is a drawing made from a microphotograph of a nine-day human callus which shows more clearly

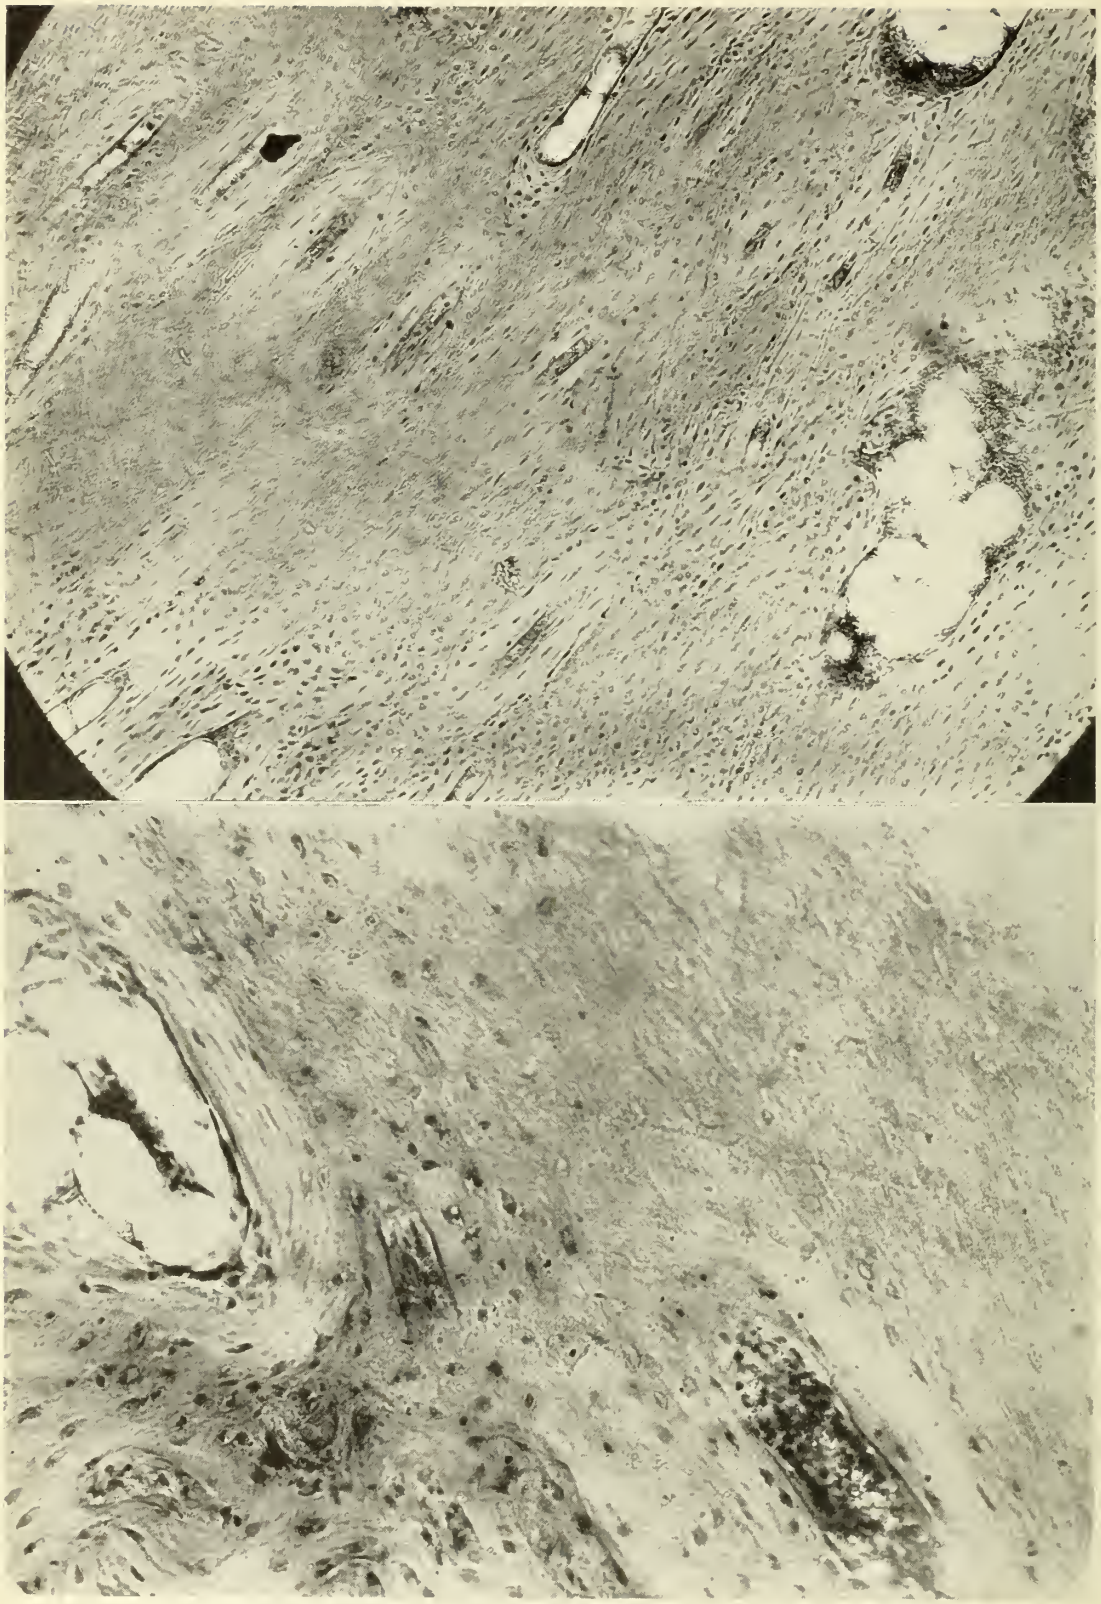

Fig. 9 (*above*). One of included fragments of Figure 8 (× 150).
Fig. 10 (*below*). High power of section of Figure 9 (× 375).

the features noted in the last figure. The background again is the loosely meshed tissue of growing fibroblasts with its accompanying capillaries—granulation tissue. In it is the lace-like mesh of calcium deposition. Any single mesh is found to consist of a central capillary surrounded by an area of fibroblasts and the deposition of a rough ring of calcium outside this area —that is, in the relatively avascular zone. The cells lying within the calcium deposition again are identical with those comprising the areolar tissue outside, and the areas of calcium deposition merge very gradually into the matrix of the areolar tissue wherever they do not link up with other areas of calcium deposit. (A) represents a capillary, (C) the areolar tissue which surrounds the capillaries, and (B) the deposition of calcium about the cells in the outer zones of (C)—the relatively avascular areas.

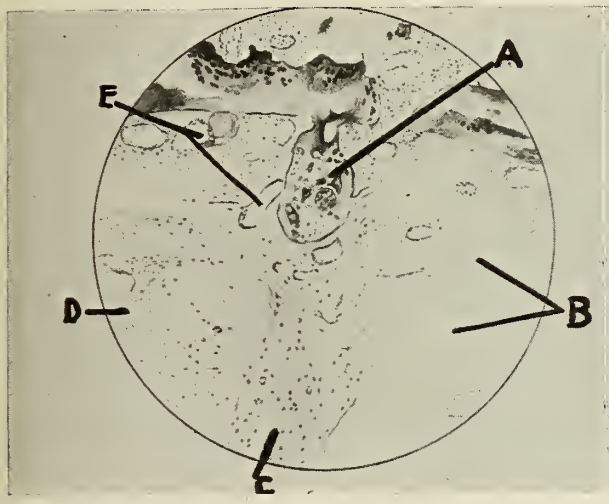

Fig. 11. *A.* Cartilage. *B.* Adjacent cortex. *C.* Callus. *D.* Normal cortex. *E.* "Cyst" formation.

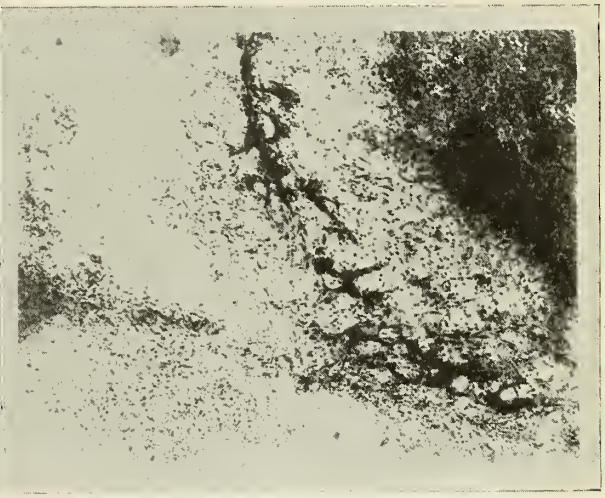

Fig. 12. Three-day human callus.

Figure 14 is a high power microphotograph of the preceding one, designed to bring out the details. One can see clearly the identity in morphology of the fibroblasts and the bone cells, the background of loose meshed fibroblastic areolar tissue and the mode of formation with the central capillaries, the surrounding areolar tissue and the calcium deposition in its outer relatively avascular zones. Also clearly demonstrated is the gradual merging of the calcium-impregnated areas with the collagen background of the areolar tissue, so that in spots it is difficult to tell just where calcium begins and ends. One is struck by the fact, after the study of many of these sections, that if this were a water color and it were possible to wash out the deep pink of calcium the resultant picture would be the classical one of granulation tissue, although no morphological change would have been effected. Between this early bone and granulation tissue there is no appreciable difference save that some process has deposited calcium in a constant pattern throughout the granulation tissue. How is this done? Is this a cell activity or a purely physico-chemical process? Where does the calcium come from and why does it deposit as it does?

Figure 15 is a drawing representing the appearance of a microphotograph of callus appearing in muscle adjacent to but not connected with a fracture of a human humerus of twelve days' duration. It was recovered at operation. There are several points of significance in it. In the first place, this new bone formation has occurred in muscle tissue unconnected with bone. Bone has appeared without a bone nidus for growth, unless we are to premise the wandering of osteoblasts from the fracture site to the site of bone formation in the muscle. Without that premise we must assume a local metamorphosis of some other cell into a specific bone-forming cell, or a process which occurs without the action of any functionally specific cell. In the second place, we must consider where the calcium comes from which is utilized to form this new bone and how it is utilized. Morphologically one notes in this section all the features seen in previous sections, including the diversity of tissue present, the morphological identity of the cells, the typical arrangement of the new-formed bone with its central vascular channels (B) surrounded by areolar tissue and, in the avascular zone, the newly deposited calcium (C). The degenerating muscle fibers are seen at (A).

Figure 16 gives another example of early callus. It shows again the typical arrangement of the new-forming bone and, in addition, emphasizes the apparent diversity of tissues present and the extremely gradual merging of the one into the other. It emphasizes the point that these tissues at this stage are not to be differentiated by cellular morphology, but by the differences in background. Here we find, with practically identical cell types morphologically, tissues which we can call bone, hyaline cartilage, fibrocartilage and fibrillar connective tissue, purely because of the ground substance in which the cells lie. These ground sub-

stances are or are not the product of the cells. They vary, although the cells show no visible evidence of functional variation. Moreover, these backgrounds merge very gradually one into the other. Is this evidence of varying degrees of functional metamorphosis finally become so-called scar tissue with long flattened cells lying between the collagen fibrils comprising the ground substance.

Figure 19 represents a microphotograph of the callus adjoining one of the bone ends at a fracture site. This

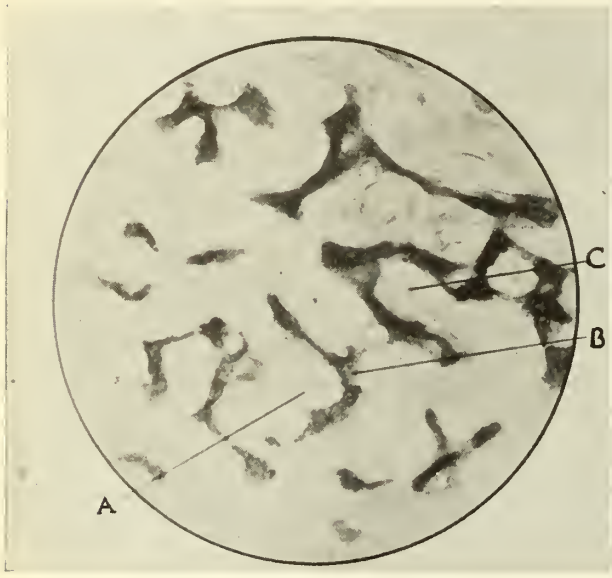

Fig. 13. Nine-day human callus.

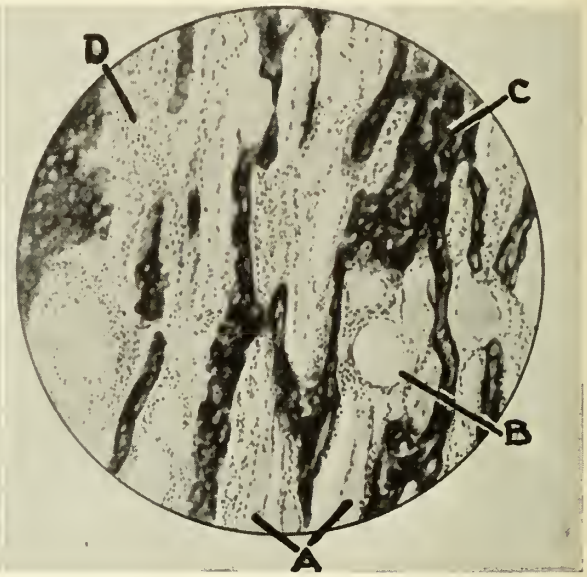

Fig. 15. Human callus, 12 days' duration. *A*. Degenerating muscle fibers. *B*. Blood vessel. *C*. Calcium. *D*. Areolar tissue.

of cells without morphological change? Or is it evidence of the lack of specific connection between the functioning cell and the ground substance in which it is embedded?

Figure 17, a microphotograph of another specimen of early callus, again focuses attention on all the points cited in the discussion of the preceding figure. These specimens of early callus are well worth careful and detailed study as to all the points cited in connection with them.

Figure 18 shows a specimen of callus of later date than shown in the preceding illustrations. The formation of the Haversian canal systems in spongy new bone is now apparent. The avascular zones are the sites of the intercommunicating bands of calcium deposition. These bands are becoming more sharply defined. The gradual merging of the ground substance of bone and connective tissue, although still present in numerous areas, is becoming a less marked feature. The calcium bands seem in general to have become more sharply defined and to have definite sharp margins. Cell morphology is still generally undifferentiated, although it is becoming apparent that those cells which lie in the denser and more rigid medium, which is becoming constantly more dense and compact because of continued calcium deposition, are beginning to look flattened out and elongated. Casting about for comparison, one calls to mind that in loosely meshed new growing connective tissue in a healing process one observes an identical change as that tissue becomes denser and denser, to is a late stage in the process. Again we see the characteristic pattern of the new bone formation, heretofore commented upon; again the diversity of tissue types. In the lower left quarter of the picture the merging of one background into the other is apparent. Elsewhere the definition is sharper. Morphological differentiation of the cells of new bone and connective tissue is difficult. Where that new bone is densest, there the cells are perhaps a little more flattened and elongated. When we look at the old very dense cortical bone, we note that the cells are elongated and flat and are therefore morphologically different from those of the newformed bone. Does this morphological change mean functional difference or is it purely the physical effect of the embedding medium? Note also in this figure the evidences of some death in the old bone cortex as evidenced by the absence of nuclear staining and the empty cell spaces. Note also that the new bone is formed about this cortical bone as a nidus and not down in the left lower quarter, where no preëxisting bone is present. Is the cortex a nidus about which the new bone forms because of the presence there of live bone cells which take part in or initiate the process, or because of the presence of the dead bone? How can the dead bone act as a nidus for new bone formation?

In *Figure 20* we have a microphotograph of tissue taken from between the bone ends of a fractured human femur at the end of twenty-eight days. There was considerable motion at the site of fracture. The diversity of tissue present is again apparent, as also is the

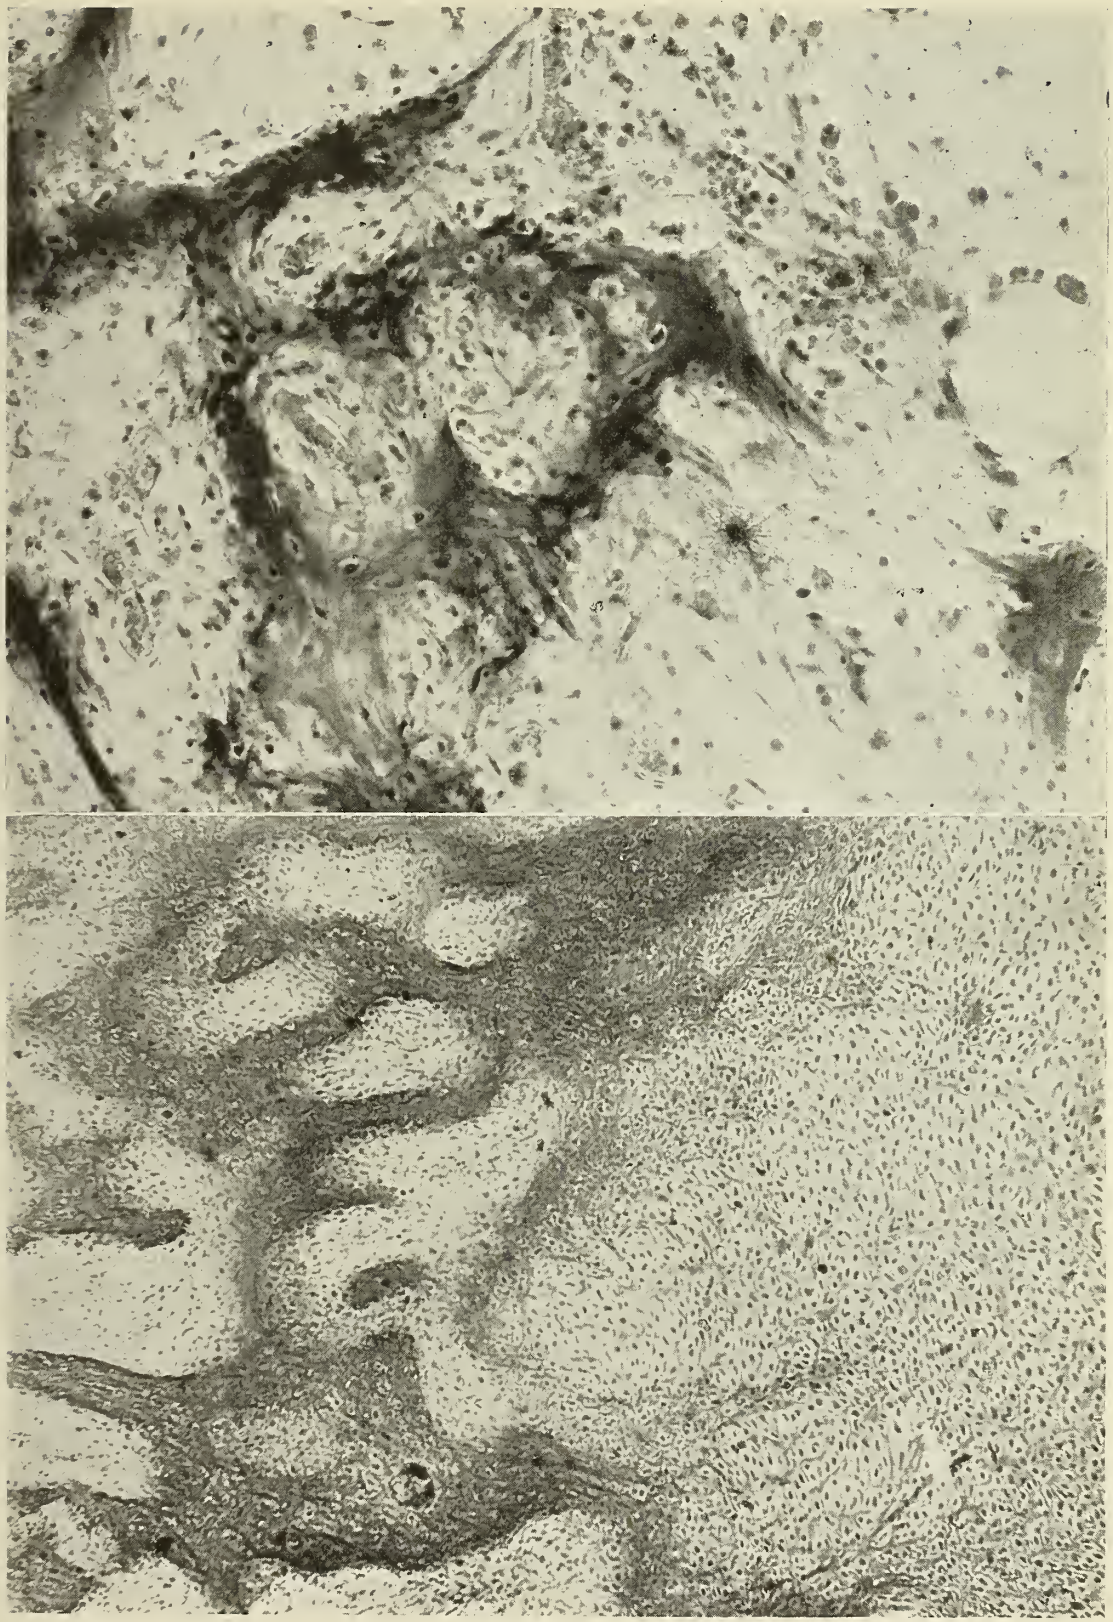

Fig. 14 (*above*). Higher power of Figure 13.

Fig. 16 (*below*). Early callus.

pattern common to new bone to which attention has been called in previous figures. In a low power picture, such as this, cellular morphology cannot be the object of accurate observation. One notes readily, however, a larger amount than usual of cartilage. Whence is this tissue derived and how? If morphology is to count for much, surely we should suspect this tissue of specificity if we are going to talk of specific osteoblasts *per se* or by adaptation or metamorphosis. Frequently repeated one meets the assertion that undue movement at the site of a fracture favors the presence of cartilage in the callus. What is it that such mobility at a fracture site can influence to have such effect, if this story be true?

Having viewed the observed facts as to what actually happens and propounded some of the questions which these observations have brought into our minds, let us go now into the question as to how this process which we have studied is accomplished.

We have been accustomed for years to talk of osteoblasts. These we have conceived to be specialized forms of connective tissue cells—cells having the specific function of forming bone by the laying down of calcium salts (?) about them in the intercellular substance in which they happen to be. Assuming for the moment that this idea is a correct one and that we are on safe ground, let us follow out the story. At the time of fracture we have seen that there is hemorrhage from the bone ends and in the traumatized soft parts, with some tissue death in both those structures. As a result of the effused blood (which is a marked chemical irritant when free in the tissues), of the physical insult, and of the mechanical blocking and destruction of both blood and lymph channels, there is added a profusion of exudate rich in fibrin. The necessary ferments being at hand, set free or activated by tissue death, the hemorrhage and exudate clot. That is, they lay down an entangling fibrin network between and about the bone ends and in the adjacent soft parts to which they have access. The remaining fluid portion of the blood and exudate follows tissue planes to the surface to appear eventually as the extensive ecchymosis seen in fracture cases. The fibrin clot is promptly organized as granulation tissue by the ingrowth of capillary buds and their surrounding fibroblasts. This tissue is derived solely from the connective tissue in the structures involved—periosteum, endosteum, vessels, fasciæ, the stroma of muscle tissue and the areolar tissue between them. Experimentally, as we have seen, it is possible to prove that under given conditions most of this may come from soft parts without the bone. In a subperiosteal fracture it must obviously be derived totally from the soft parts of the bone—periosteum, so-called endosteum, and the areolar tissue of the marrow spaces. This granulation tissue, from wherever derived, surrounds the bone ends and joins them one with another and with the adjacent and available soft parts. *It constitutes the healing of the wound in bone,* just as similar tissue constitutes the healing process in muscle, cornea, liver or other tissue. Up to this point we have been talking of observed facts. Assuming the osteoblast as an identity, we may now theorize as to what happens to cause calcium deposition in the manner in which we have seen it deposited to form a calcium matrix granulation tissue called bone instead of a collagen matrix connective tissue. In this granulation tissue must be enmeshed such osteoblasts as were freed without death by the mechanical violence of the fracture rupturing the cell spaces. A certain number of osteoblasts are killed by the violence plus the inflammatory reaction, and the bone matrix occupied by them is autolyzed by ferments freed by tissue death and is partly absorbed but mostly remains as a high calcium concentration locally in the tissue fluids. The fate of this matrix is also an observation of fact and not theory. The exact state in which this calcium exists is unknown. The exact state in which the calcium of the blood exists is not known. Both these points will be referred to again. To return to our osteoblastic muttons, other osteoblasts grow out from the ends of the bone, invading the granulation tissue and laying down their calcium matrix about them as they do so in increasing density. The very early callus of thick gelatinous fibrin-rich exudate invaded by granulation tissue with relatively little calcium becomes harder and firmer, but completely retains its form of granulation tissue. Morphologically there is no way of telling these osteoblasts from the cells of connective tissue, or the granulation tissue from the early callus, as we have seen, except by the presence of a calcium deposition which merges imperceptibly into the collagen of the connective tissue fibrils. In many of the experimental specimens actual fibrillar striations are seen directly continuous with those of adjacent connective tissue. The calcium involved must be part of the cells' metabolic activity, and

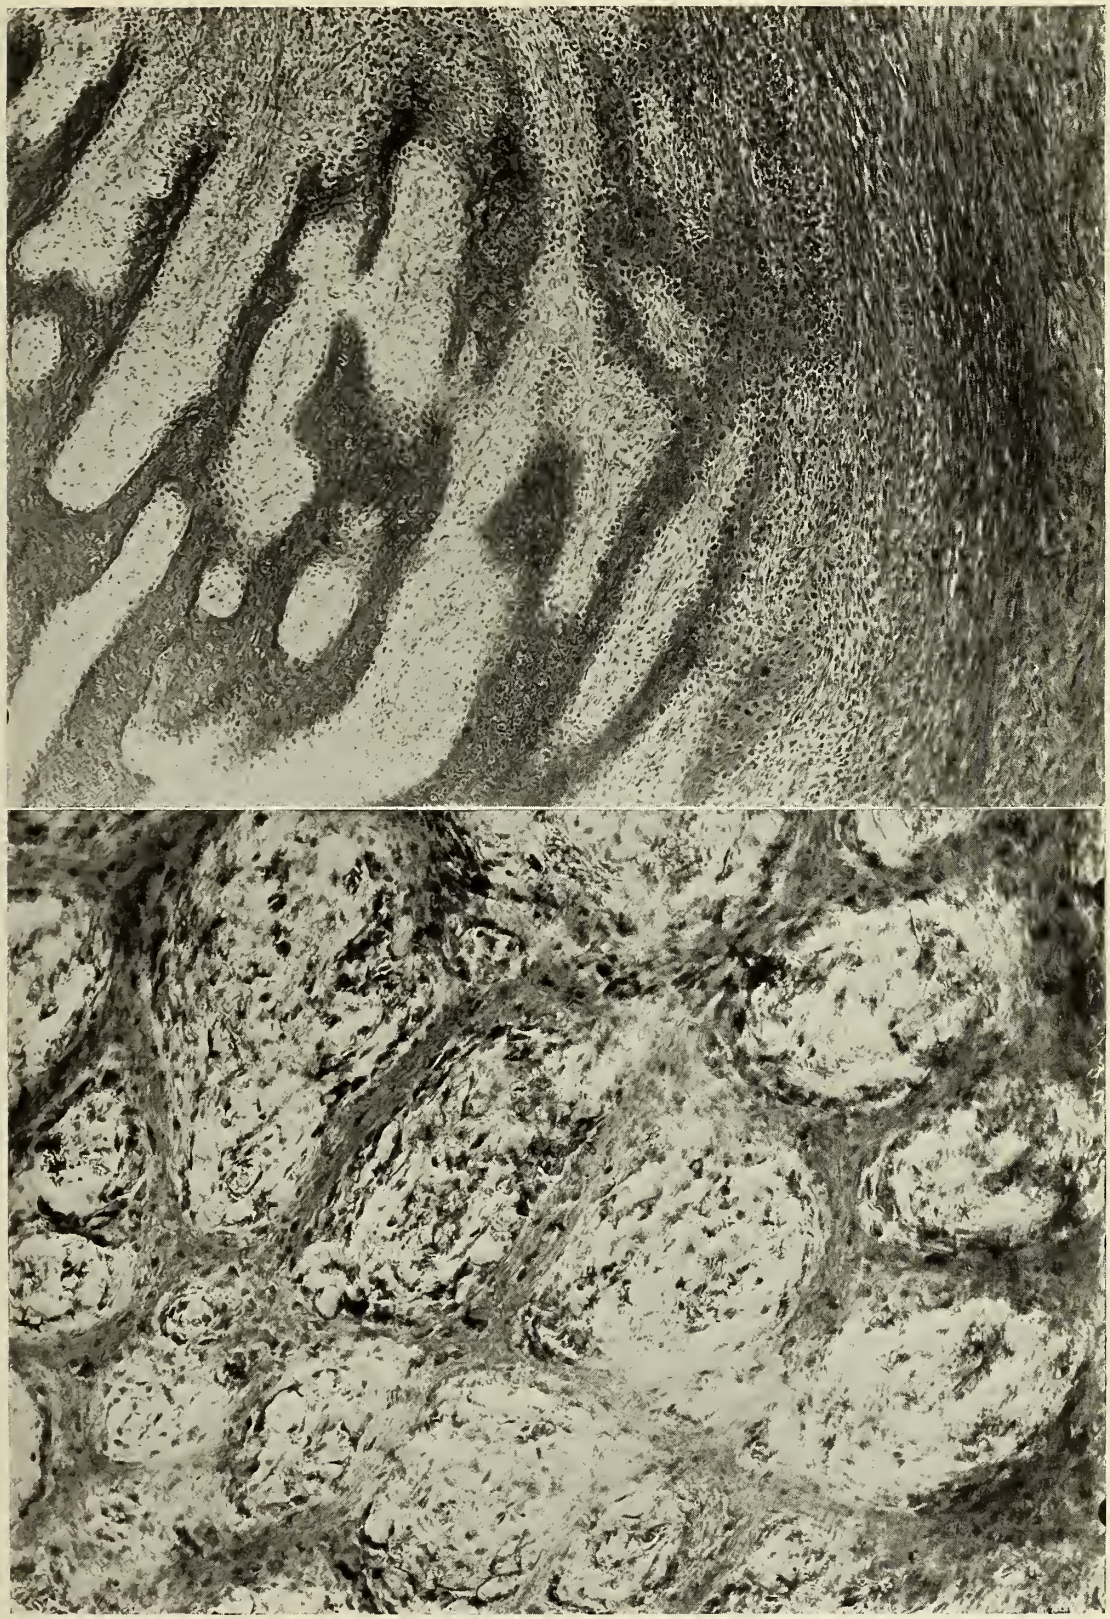

Fig. 17 (*above*). Early callus. Compare Figure 16.

Fig. 18 (*below*). Late callus. Compare Figures 16 and 17.

its source should logically be, and has been presumed to be, the blood stream. The argument as to the exact source of these specific osteoblastic cells, whether from periosteum's cambium layer, bone, or endosteum—which has been in progress since the days of Barth,[8, 9] Ollier,[10] Duhamel[11] and John Hunter,[12] through MacEwen[13] to modern times—can be epitomized in the statement that under the osteoblastic theory from today's viewpoint the cells are derived from all three of the sources mentioned.

Bony callus having been formed thus, the molding or architectural story from then on is a physical one and has no bearing on the formation of bone.

Here we have what sounds like a pretty straightforward story. Yet there are numerous flaws in it. Sometimes the activity of these specific cells is apparently interfered with. The purely mechanical bar of interposed tissue or widely separated fragments we can, of course, dismiss as readily understandable, no matter what idea we may have as to the mechanism of bone repair. But frequently under ideal conditions—that is, with early and accurate reduction and treatment thoroughly approved by textbook standards—we are confronted, perhaps, by an exceptionally slow callus and bone formation which we call delayed union. Or we get an absolute failure of callus or bone formation which we call a non-union. Or, still again, we get good callus, satisfactory *x*-ray evidence of bony union with solidity of the parts, only to find absorptive changes coming on with marked decalcification at the fracture site and eventually a fibrous union remaining. This is not an unusual story in fractured neck of the femur, the proximal neck fragment absorbing after as long as six to nine months right down to the intertrochanteric line. Under any of these circumstances we are given to stimulating these specific bone-forming cells in various ways. Empirically it has been discovered that they can at times be awakened from their unexplainable apathy by various forms of insult. When so aroused they seem to proceed to lay down calcium, as a well-behaved osteoblast should do, and bony union occurs. At other times such insult seems to be of no avail, no bony union occurs and we are left with a so-called non-union. Some of the physical means of stimulation used are frequently repeated tappings over the fracture site with a light mallet, repeated grinding together of apposed surfaces with moderate force and only slight motion range, repeated needling of the fracture site, exposure to *x*-ray and weight-bearing with support. The chemical means include the injection at the fracture site of numerous irritants from blood through a long range of chemicals. One might feel, perhaps, that these cells failed because the source for their calcium metabolism, *viz.*, the blood stream, was deficient in amount or in kind. Feeding these patients calcium or phosphorus or both has no appreciable effect, nor in my own experience has the feeding of vigantol or irradiated ergosterol, with the idea of increasing the blood phosphorus, or of parathyroid, with the same idea in mind. Some years ago Tisdale[14] reported the consistent finding of a raised blood phosphorus in adults during fracture healing extending over a period of weeks, and construed the phosphorus rise as an indicator of increased calcium activity. The absence of such a rise was presumptive evidence of a threatened non-union. He found such a conjunction in a few cases. Subsequent workers have consistently failed to check on his findings. Working with Eddy,[15] the bio-chemist at Teachers College in New York, on a series of cases in New York Hospital and other hospitals, I could find only partial corroboration of Tisdale's conclusions, but found that the same phosphorus rise occurred in any extensive soft part healing—such as large granulating operative wounds, extensive granulating burns and extensive fibrosis due to phthisis. Also, the extent and amount of callus formation bore no definite relation to the phosphorus rise. Eddy's impressions were not in exact accord with this opinion. His chief interest lay in the methods used to determine the blood phosphorus figures—mine in the clinical study of the cases. To date there is no corroboration over a year's period in the Fracture Service at the Presbyterian Hospital in New York, where a blood phosphorus and blood calcium is taken weekly on every fracture case. Cases showing actual decalcification at the site of fracture have shown normal calcium and phosphorus blood findings. This is true also of fractured neck of the femur cases. It seems difficult, then, to blame non-union on lack of blood calcium to provide to the osteoblasts. By some of those who hold to the osteoblastic theory the problem is now being worked on, under many technical difficulties, on the basis of

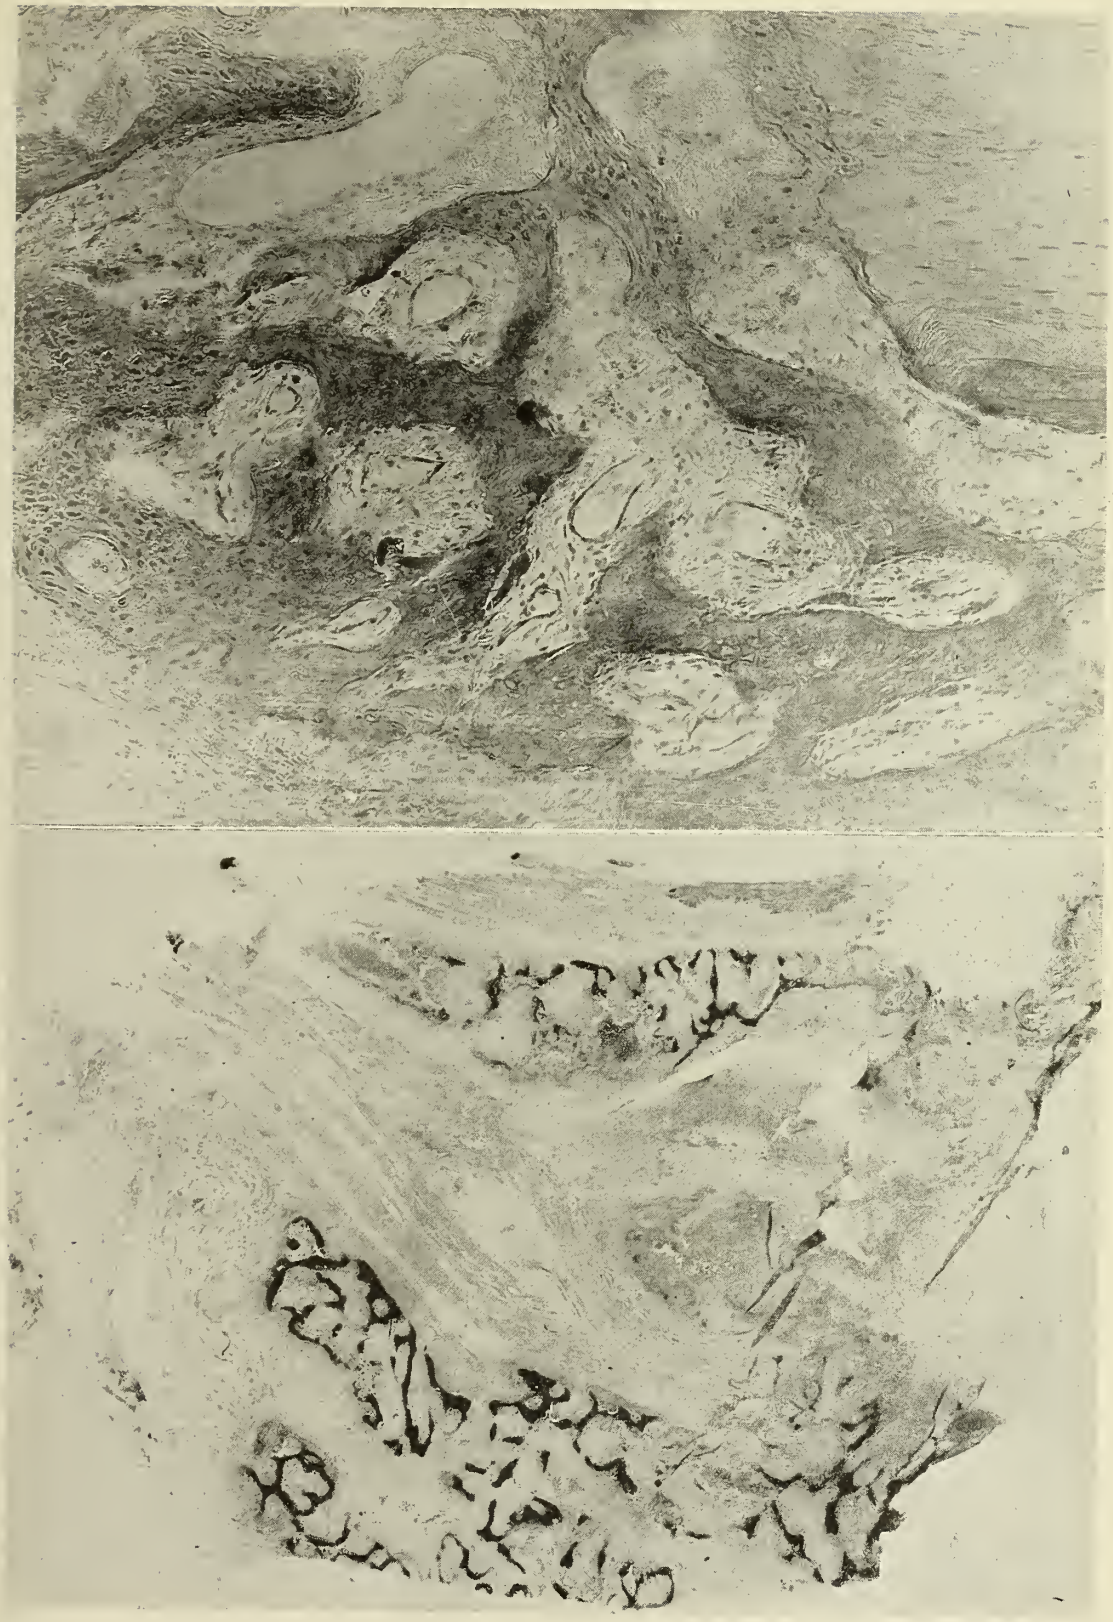

Fig. 19 (*above*). Late callus about broken end of bone.

Fig. 20 (*below*). Fractured human femur, 28 days. Considerable motion at fracture site. Tissue removed at operation from between bone ends.

the relative proportions of diffusible and non-diffusible calcium present in the blood stream.

Having considered these points, another series of observed facts appears which are upsetting. If we are to regard osteoblasts as specific, certainly we must so regard cartilage cells. At the site of fracture in the shaft of an adult long bone there is surely no cartilage, and yet callus in its formation, as one can see from our sections, contains bone laid down both in cartilage and in connective tissue. More than that, the bone form of matrix with the cartilage type of cell exists in callus—an association hard to correlate with a specific osteoblast, since morphologically no cells even remotely resembling osteoblasts are present, and yet bone is present. We call to mind also the lack of any distinctive cell type in many of these sections. The cell type has apparently little correlation to the type of intercellular substance.

At different times we note active bone formation in tissues far removed from bone as the result of injury, disease, or chronic irritation. Under the microscope this is morphologically real bone with Haversian canals, not a mere calcification. It is found in chronically inflamed and fibrotic tonsils, in abdominal scars, and in the late stages of arteriosclerosis in the outer walls of the vessels where run the vasa vasorum. It is also found following trauma to muscles, as the so-called traumatic myositis ossificans (in the true case it has no connection with bone), and it is found in the form of rider's bone. Experimentally it is produced by numerous methods. If we tie off the intrinsic circulation of a rabbit's kidney, leaving only the capsular supply with or without omental aid, we will get true bone formed in a certain percentage of cases. Neuhof[16] has secured it in fascia lata transplants into the bladder wall. The only constant factor in all these instances of abnormally situated bone formation is a circulatory disturbance, with some death of tissue. If we hold to a specific osteoblast we must then believe that these abnormal sites for bone production are the results of the activities of osteoblastic rests of fetal origin, or that under certain indefinite conditions of which we know only two constants—circulatory disturbance and slow tissue death—ordinary fibrillar connective tissue cells may by metamorphosis become osteoblastic in function. The why and wherefore of that metamorphosis is beyond our ken.

To go back to our non-union for a moment. When other means fail, Bier's hyperemia sometimes succeeds—this is essentially the introduction of an artificially produced vascular disturbance into the picture—and, just as in tying off the vessels of a rabbit's kidney, sometimes it works and sometimes it does not. Nor have we any means of telling just which result is going to be effected in any given case. When all other means fail we are driven to operative procedure, the most effective method being some form of bone graft. If we hold to a specific osteoblast or an oseteoblast by metamorphosis it stands to reason that we must believe we are transplanting live osteoblasts, or are creating conditions favorable for the metamorphosis of osteoblasts from connective tissue cells, or both. Some things we know we do by operating—we kill some bone by trauma, we invade the soft parts which in healing produce granulation tissue and we change the circulatory status.

We can now take up some of the more recent observations on the bio-chemistry of this process. The work of Wells,[17, 18] Howland,[19, 20] and others has established many apparent facts in connection with the blood and tissue calcium and phosphorous content in health and disease. It has also been shown that hyaline cartilage in the presence of calcium inorganic salts shows a marked avidity for the adsorption of these salts. It has been shown also that under proper P^H conditions these calcium salts can be caused to precipitate or deposit in the hyaline matrix. Watts[21, 22] has shown that the form in which calcium exists in bone, a homogeneous mass, is entirely different from the form in which calcium appears when precipitated from solution *in vitro*. By alterations in the P^H it has been observed also that calcium in colloid combination can be deposited from that combination without any cellular activity. Bassett[23] has indicated a complicated organic calcium combination of large molecular size, which contains calcium and phosphorus with carbonate attached as CO_2 and which he calls hydroxyapatite. He has shown that this compound is capable of stability in both blood and tissues. Robison,[24, 25] of England, has produced evidence to show that in calcium compounds showing this same adsorption into

cartilage the precipitation of the calcium in the cartilage may be induced by the activity of a phosphatase or esterase which by splitting a hexosephosphoric ester frees phosphoric acid and may therefore bind the calcium. Moreover, it is conceivable that by alterations in the P^H of the medium in which this reaction takes place, it can be slowed up or stopped. All ferments, as we know, are active to their full extent only in the presence of a certain P^H. Altering that P^H will slow up the ferment activity or even stop it, so that the normal absorption of calcium which constantly goes on under those circumstances might even exceed the amount of calcium deposition and decalcification of bone might occur. Not infrequently we clinically observe such decalcification—here is a much more logical and simple explanation of it than any that can be given under our osteoblastic theory of bone origin.

Considering all these factors, it becomes apparent that if we are to disregard cell activity we have to consider what could vary the local P^H in order to explain failure of calcification, slowness of calcification, normal calcification and even decalcification. It becomes apparent that we have a single explanation of all these phenomena within our grasp. As we have pointed out, the one constant factor in the production of bone by injury, disease or experiment is circulatory change. We have seen also that the one constant factor in the recognized forms of treatment for delayed and non-union has been circulatory change. It is logical to feel that both qualitative and quantitative local blood supply changes will induce local P^H changes. Experimentally this has been shown to be true (by the use of quinhydron or hydrogen electrodes in the tissues and a string galvanometer as a potentiometer to record changes in potential) in acute inflammatory processes in the soft parts. It requires little change in P^H, however, to affect ferment activity, and the slight changes necessary are unmeasurable accurately in the tissue fluids by our present means because of the range of instrumental error, as well as the discrepancies due to purely physical causes such as muscular contractions, circulation, etc. We can say, however, with reasonable certainty, that quantitative and qualitative change in the circulation locally very possibly may induce local changes in P^H, even when slight in extent. Here, then, may lie one phase of our story. Dependent upon the circulatory status of the soft parts, in the bone and in the adjacent tissues as well, will depend the P^H of the granulation tissue produced from those soft parts. On that P^H will depend whether ferment activity is normal, slow or absent—that is, whether calcium deposition is normal, giving union; or slow, giving delayed union (if slightly in excess of the normal absorption process which is constantly going on) or non-union (if it just about keeps pace with this absorption); or whether actual decalcification occurs because there is no calcium deposition occurring to offset even the normal absorption process in the bone. The ferment production may be the result of tissue death—and results wherever a certain amount of connective tissue death occurs.

Why, then, if the blood calcium and phosphorus are normal, does not calcium deposition as bone occur more frequently where there is tissue death with circulatory disturbance?

On this point I will cite work[7] which is now in progress, in so far as it has gone.

If we resect 2.5 cm. of a dog's radius and throw it away, leaving the gap in bone to heal as it will, we get a fibrous union filling the gap between the two bone ends with a little ossification just adjacent to the bone ends where we have killed some little bone by our operative procedure.

If, instead of discarding the resected portion, we remove all periosteum and endosteum and break it up into chips and place *them* in the gap, we get a solid bony union, although, as we have seen from our sections, these bone chips are dead and are autolyzed, at least in part.

If, to make sure of their death, we boil the fragments before putting them back, we get bony union notwithstanding.

If we decalcify these fragments before we put them back, *we get no evidence of bony union.*

Obviously, viability being disposed of as a factor, and everything else except the calcium being disposed of as a factor, the rôle of these bone chips seems to be to supply calcium for the calcification of the granulation tissue constituting the healing process.

Therefore, I have resected in other dogs the same amount of radius, discarded the fragment and placed in the 2.5 cm. gap powdered sterile $CaCO_3$ and $Ca_2(PO_4)_3$—supplying an artificial source of calcium in the gap previously filled by bone—and *solid bony union has resulted.* Similar

procedure using sterile powdered calcium hexose phosphate has again given solid bone in the 2.5 cm. gap.

If, before putting in the calcium, some of the dog's blood was defibrinated and the fibrin placed in the gap, the union was more rapid. As control animals with merely the fibrin placed between the fragments gave fibrous union, we can conclude that the rôle of the fibrin is merely to aid in the more rapid organization by granulation tissue. It is possible also that the fibrin has a similar affinity for calcium to that of the hyaline of cartilage. The hyaline of cartilage and the collagen of new-formed connective tissue are very closely allied chemically, and such affinity in collagen has been shown to exist. Such an affinity in the fibrin would tend to hold the calcium for local use and to prevent its dispersion by the local circulation.

Here, then, we may have good logical reason for the occurrence of these delayed unions, nonunions and decalcifications, even in the presence of normal P and Ca. The calcium source for calcification of the granulation tissue is local and is the dead bone at the site of fracture, autolyzed by ferments set free or activated by tissue death and held in situ by the affinity of fibrin (?) and the collagen of granulation tissue and deposited in that granulation tissue to form bone by another ferment activity, that of a phosphatase being used purely as an example. The vital process would then be ferment activity in the presence of a local calcium source, and the completeness or failure of the process would depend upon the local P^H of the tissue fluids induced by the local circulatory status. On this basis bone formation would not occur in soft parts where tissue death and circulatory disturbance co-exist unless there were a local concentration of calcium at the site (regardless of what the blood phosphorus or calcium might be) and unless the circulatory change were such as to produce proper tissue fluid P^H conditions. The factors which might cause local concentration of calcium in an isolated soft part region, thereby providing the local calcium source, remain to be determined. It has been shown that the growth of certain bacteria in the soft parts can induce such a local calcium concentration. This and other factors capable of doing the same thing are under investigation.

The possible conclusions we may draw from the material herein presented are as follows:

1. Fractures always heal, unless there is a mechanical bar to tissue growth.

2. The healing is accomplished as with wounds elsewhere by the growth of granulation tissue.

3. This granulation tissue is derived from the wounded soft parts of the bone—periosteum, endosteum—and the areolar tissue about the vessels in the marrow cavity and elsewhere. If there is tearing of the periosteum it is derived from the soft parts about the bone as well, in proportion to the access allowed them to the fracture site. Sometimes the major part of this granulation tissue comes from the soft parts about the bone.

4. Delayed union is a failure of the healing tissue to calcify at the average rate.

5. Non-union is a failure of the healing tissue to calcify at all.

6. The source of calcium for this calcification is dead and autolyzed bone at the site of fracture and not the blood stream.

7. Vascular changes probably induce local tissue P^H changes which may strongly influence precipitation of calcium salts from solution or colloid combination or ferment activities on large radicles of organic calcium salts—such as hydroxyapatite or calcium hexose phosphate.

8. Given tissue death, a local calcium source, a vascular status producing the proper P_h, and granulation tissue, bone will form without the presence of any bone cell.

9. Bone as a calcium source can be experimentally replaced by both inorganic and organic salts of calcium (hexose phosphate). Either precipitation or ferment splitting activity may be responsible for the calcium deposition; the latter seems the more probable.

10. Bone and soft part circulation are of prime importance in the process of calcification of fracture healing and should, therefore, be prime objects of attention *early in the bone healing process.* The time to use elevation, heat, massage, diathermy and active exercise is at that time, if possible; it is much more important than later in the course.

11. Mouth administration of Ca, P and similar drugs is ineffective. If calcium is needed it must be supplied locally and not via the blood

stream in any individual whose general calcium metabolism is normal.

SYMPTOMS AND COMPLICATIONS OF CHRONIC URINARY OBSTRUCTION*

William F. Braasch, M.D.
Rochester, Minnesota

STRANGE as it may seem, one of the commonest human ailments is also one that is frequently overlooked; namely, hypertrophy of the prostate gland. One would naturally think that a condition so easily diagnosed on rectal examination would scarcely ever be missed. Failure of diagnosis occurs, in most cases, either because of the absence of any urinary symptoms, or because the prostatic obstruction is confined to the intravesical portion of the gland so that rectal examination gives negative results.

One would infer that in cases in which the prostatic obstruction is sufficient to cause considerable retention of urine, the patient would be aware of some urinary symptoms which would call attention to the condition. However, this is frequently not the case, since it is not at all uncommon to find residual urine to the amount of 500 c.c. or more without the patient being aware of its presence, and with no urinary disturbance noticeable to the patient. Probably the increase in residual urine is so slow and insidious that the patient is not aware of any additional discomfort. It is surprising how the human system will accommodate itself to the presence of a large amount of residual urine and how all other functions proceed as regularly as though nothing had happened. Apparently, however, there is a limit to the amount of urine which can be retained in the bladder without causing disturbance of renal function. This limit probably varies considerably in different persons, depending on a variety of factors, chief of which probably is the degree of protection against back-pressure offered by ureteral peristalsis and the ureterovesical mechanism. When this barrier has been broken down and the function of the kidneys is interfered with, symptoms arise which are not referred to the urinary tract but which are included in the wide range of symptoms accompanying renal insufficiency.

Among the secondary symptoms more commonly observed are anorexia, nausea, vomiting, headache, dizziness, loss of weight, general weakness, and other signs of constitutional disturbance. Therefore, when a male patient aged more than forty years comes to the physician with headache, loss of appetite, occasional nausea or even vomiting, with pain referred to the epigastrium, or with such symptoms as backache and gradual loss of weight, it behooves him to make a rectal examination in the course of the general examination, and to determine whether there is any evidence of prostatic enlargement or other evidence of urinary retention. The complete medical examination in every case, and particularly in the adult male, should include a rectal examination, and unless this is made as a routine, many clinical conditions will remain undiscovered. It is curious that there should be an apparent prejudice against rectal examination, when by it data are so easily discovered which may be of such fundamental importance in ascertaining the cause of symptoms.

It is not at all uncommon in my experience to observe patients concerning whom a previous clinical diagnosis of nephritis has been made and in whose cases the results of general examination and the laboratory data suggest advanced nephritis. Many of these patients have been placed on antinephritic treatment, including dietary precautions, for months before the true condition is recognized. The similarity between the clinical data observed in cases of nephritis and those in renal insufficiency resulting from urinary retention, often is striking. Anorexia, nausea, loss of weight, weakness, headache and dizziness are common to both conditions. The data obtained on urinalysis are usually similar. The total output of urine in twenty-four hours is usually more than 2,000 c.c. in both conditions, and the specific gravity is usually low, averaging from 1.006 to 1.010. The excretion of phenolsulphonephthalein in two hours is often

*Read before the Northern Minnesota Medical Association, Bemidji, Minnesota, September 2 to 3, 1929. From the section on Urology, The Mayo Clinic, Rochester, Minn.

only a trace, with marked delay in time of appearance. As estimated, the blood urea and blood creatinine are usually markedly elevated; of the former often there are more than 100 mg. and sometimes more than 200 mg. for each 100 c.c. The blood pressure is usually markedly elevated; a systolic pressure of 200 mm. of mercury is not an uncommon occurrence.

Among the most valuable methods of clinical differentiation is the ophthalmoscopic examination. Characteristic retinal changes would almost necessarily be present with nephritis sufficiently advanced to cause clinical signs, such as those described. However, when urinary retention is the underlying factor, marked retinal changes are usually absent.

As an illustration of this differentiation may be mentioned a case which came under my observation not long ago. In the course of general examination the examining physician found clinical data which led him to believe that the condition was one of nephritis. An ophthalmologist was called in to make a retinal examination and when he had finished said, "This patient does not have nephritis; he has enlargement of the prostate gland." He arrived at the conclusion purely by differentiation, realizing that a patient with clinical evidence of advanced nephritis, and with normal eyegrounds, could hardly have anything else than urinary retention to account for his condition.

An interesting feature in the differentiation of nephritis and the insufficiency of renal back-pressure is the frequent absence of parallelism in renal back-pressure between the retention and excretory renal functional tests. As a result of interference with renal drainage caused by back-pressure, the excretion of dyes, such as phenolsulphonephthalein, is greatly diminished. It is not uncommon to find that only a trace of phenolsulphonephthalein has been excreted two hours after its intravenous injection, giving the impression of widespread renal destruction. On the other hand, retention tests may show that the blood urea is only moderately elevated and the blood creatinine may be practically normal. In contrast, there is usually closer parallelism between the excretory and retention tests in nephritis. If, in a case of evident renal insufficiency, there is any question as to the predominant etiologic factor, differentiation can be made by renal functional tests following drainage of the urinary tract. If the renal insufficiency is temporary and is caused by urinary retention, the laboratory data will undergo a great change when drainage is reëstablished. First to improve will be the blood urea, which may drop 30 or 40 mg. within a week. The excretion of phenolsulphonephthalein gradually will improve, and in the course of several weeks will approximate normal. How different the picture is with true nephritis or when the kidneys are permanently injured. It is then only with great difficulty that the blood urea can be reduced, and the excretion of phenolsulphonephthalein may remain but slightly improved, in spite of every effort.

It is strange how frequently patients present themselves with symptoms referable to the alimentary tract entirely. It is not uncommon for patients to give a history which can easily be regarded as typical of gastric carcinoma, such as vomiting, epigastric pain, loss of weight and cachexia, all of which can be explained by renal insufficiency secondary to urinary retention. It is curious that many patients with prostatic hypertrophy will also complain of considerable constipation. Whether the enlargement sometimes acts as a mechanical factor in the rectum or whether it is a reflex phenomenon from irritation in the prostatic region is difficult to determine.

The physical evidence of urinary retention other than that which may be obtained from prostatic enlargement must be considered. One might think that an overdistended bladder could be made out rather easily on abdominal palpation. However, this often is not the case. It is surprising to what extent the bladder may be distended and still be difficult to discover on either abdominal or rectal palpation, or by percussion. When there is an evident abdominal tumor in the median suprapubic region, one must, of course, infer vesical overdistention, bearing in mind, however, the other abdominal conditions which may cause tumor similarly situated. The bladder, however, does not always distend uniformly, so as to cause a symmetric tumor in the median suprapubic region. In fact, it happens frequently that there is unilateral enlargement of the bladder, for half of the musculature of the bladder may give way and that half may be-

come distended, while the remaining portion of the musculature of the bladder hypertrophies. As a result of this, the tumor may be felt entirely in either the right or left lower abdominal quadrant. I distinctly recall a case of this kind in which a surgeon had felt a cystic mass in the lower right quadrant of the abdomen and had advised immediate operation for abdominal tumor. Although the patient did not have urinary symptoms and although on rectal examination there was little, if any, prostatic enlargement, the tumor disappeared on introduction of a catheter into the bladder.

One might expect that examination of the urine would call attention to the presence of urinary retention. However, in many cases of retention, urinalysis gives negative results or reveals, at most, occasional leukocytes or erythrocytes. Needless to say, the presence of even a few cells should always lead to further investigation of the urinary tract. With prolonged urinary retention of marked degree, there is usually definite reduction in specific gravity, which also might call attention to possible involvement of the urinary tract.

Of greater value would be the evidence obtained by renal functional tests. As the result of prolonged renal back-pressure there is often excretion of only a trace, or an extremely low percentage, of phenolsulphonephthalein, and with the low excretion of dye the blood urea is usually distinctly higher than normal. There is lack of parallelism between the retention and the excretory tests because the amount of the dye excreted is not a true index of the secretory power of the kidney. Because of the back-pressure of the retained urine there is failure of excretion of the dye rather than failure of secretion. Frequently, the blood urea is raised only to a moderate degree, whereas the excretion of phenolsulphonephthalein is markedly reduced.

It must be emphasized that urinary retention cannot be excluded because evidence of prostatic enlargement is not felt by rectum. The following conditions may be present even though rectal examination gives negative results: (1) prostatic obstruction confined to the intravesical or median portion of the gland; (2) disturbance of innervation of the bladder, usually resulting from disease of the central nervous system, or (3) diverticulum of the bladder.

It is frequently surprising how much prostatic obstruction may be present in the intravesical portion of the gland in cases in which rectal examination reveals little, if any, enlargement. Such obstruction can be determined by means of cystoscopic examination only. The presence of retention in such cases may be surmised from the data previously described, and in case of doubt can be verified by catheterization. The degree of urinary retention is not commensurate with the degree of prostatic enlargement felt by rectum. Frequently, the prostate gland is comparatively small and still is so situated that the obstruction is great. Since the widespread use of the cysto-urethroscope, cicatricial contracture of the vesical neck also is being recognized as a common cause of urinary obstruction.

Another form of prostatic enlargement which has not been mentioned is prostatic carcinoma. This condition may be the cause of a variety of general symptoms without any subjective evidence of urinary obstruction. Chief among these is pain referred to various portions of the body. One of the commonest causes of so-called lumbago, sciatica or neuritis referred to the sacral or lumbar region or to either leg, is that caused by prostatic carcinoma. Many patients have been observed who have complained of pain referred to these regions, and of loss in weight or strength, but in whom the prostatic condition has been neglected because of absence of urinary symptoms. The abnormality of the prostate gland could be discovered only by rectal examination as a routine. It hardly would be necessary to describe the physical characteristics of prostatic carcinoma, since all are familiar with the peculiarly firm, nodular character of the gland.

Urinary retention resulting from disturbance of innervation of the bladder is common and may easily be overlooked. Such retention may be caused by disease in the central nervous system or by terminal neuritis. Although the former condition usually is accompanied by clinical evidence which would call attention to a lesion in the central nervous system, such data are often obscure, and in the early stages of the disease may be absent. On the other hand, retention existing with an evident lesion

in the central nervous system frequently is overlooked in the absence of urinary symptoms. It is peculiarly true, however, that in the presence of a lesion in the central nervous system, retention is more often present over a long period of time without causing evidence of renal insufficiency or urinary disturbance than it is in the presence of prostatic obstruction. As a result of dysfunction of the nerves supplying the bladder, the cystoscopic appearance is pathognomonic and gives a picture of the so-called cord bladder. Rectal examination in cases of this condition is often of diagnostic value. Instead of the normal prostatic fullness, a definite depression or flaccid condition of the rectal musculature in the prostatic region may often be discovered. On introduction of the finger, attention may be called to the possibility of disturbance in innervation by definite weakness of the anal sphincter and lack of muscular tonus in the rectal wall.

Another lesion which may cause considerable urinary retention is diverticulum of the bladder. Frequently the diverticula are multiple and may be even larger than the bladder itself, so that the resulting retention is of marked degree. Since the urine in cases of diverticula usually becomes markedly infected, the presence of diverticula should be suspected in every case of urinary retention with marked pyuria. Although there is usually more or less pyuria and dysuria in cases of diverticula, occasionally there are no symptoms referable to the urinary tract and on rectal examination there may be little, if any, prostatic enlargement. Diverticulum nearly always occurs secondary to some from of obstruction at the vesical neck, usually with enlargement of the prostate gland. Its diagnosis can be made either by cystoscopic examination or, better, by means of a cystogram which visualizes the diverticulum as a rounded area of sacculation extending laterally from the outline of the bladder. After the bladder is emptied, a subsequent roentgenogram usually will show that a considerable amount of the opaque medium has remained in the diverticulum.

A method which should be employed more frequently in general diagnosis, and which is easily available wherever there is roentgenographic apparatus, is cystography. The technic of making a cystogram is comparatively simple, and consists of emptying the bladder and then injecting several ounces of a solution of 5 per cent sodium iodide. Exposures are then made, from a right and from a left angle; the bladder is emptied, and a third roentgenogram is made. Not alone will diverticula be readily outlined by this simple method, but other deformity of the bladder, such as the elevation of the base that occurs with prostatic hypertrophy, sacculation, or deformity of the bladder, and filling defects which occur with intravesical or extravesical tumor may also be demonstrated. The method is a routine in every case of suspected urinary retention in the clinic.

In regard to the treatment of advanced urinary obstruction, it should be emphasized that when the bladder has been discovered to be greatly distended, it should not be emptied immediately. In fact, as soon as it is evident that a large amount of urine is being retained, it would be best to hospitalize the patient and gradually to empty the bladder. One of the favorite methods is by means of inserting an indwelling urethral catheter and elevating the receptacle into which the urine is emptied so that the bladder is gradually drained by the process called decompression. The bladder should not be completely drained in less than twenty-four hours; preferably as long as forty-eight hours should be allowed. It has recently been suggested that decompression can be accomplished equally well by gradually draining the bladder through a ureteral catheter of number 5 or 6 caliber. The treatment directed against secondary renal insufficiency consists largely of forcing fluids, both by mouth and intravenously, a diet low in protein, hot packs daily, and general care preliminary to removal of the obstruction.

AN ANOMALOUS EXTRA-VESICAL ORIGIN OF URETER*

Report of Case

Frederic E. B. Foley, M.D.
Saint Paul

THE case to be reported is of unusual interest because of its bizarre nature, the great rarity of the condition presented, and the unique surgical problem peculiar to it.

A young woman, aged 25, was referred for urologic examination July 31, 1929. She complained of continual persistent drainage of urine from the region of the vulva. The exact origin of the drainage, whether from the urethra, vestibule or vagina, she did not know. The seepage of fluid had been persistently present since birth. Its rapidity was not influenced by coughing, straining or change of position. It was continuous day and night. It appeared, therefore, to lack the characteristics of urethral incontinence. Careful inquiry elicited no history of injury or surgical procedure to account for a traumatic vesico-vaginal fistula. Menstruation was normal.

These facts of history suggested the possibility of one of the rare anomalies of extra-vesical origin of a ureter (improperly referred to as termination of a ureter). With this in mind the detailed physical examination was designed to discover such an anomalous ureteral opening if present in the external genital region, or vagina, or to determine the cervix as the source of drainage, in case of origin in the uterus or a fallopian tube.

The patient was well developed and nourished. The temperature, pulse rate and respiration were normal. She did not appear ill. The general physical examination was quite negative. Only details pertinent to the condition complained of will be given.

There was no tenderness to pressure in either flank and no reaction to Murphy percussion. Neither kidney was palpable. No tenderness and no mass was discovered in the abdomen. The reflex reactions were present, normally active and equal on the two sides. Skin sensation was grossly normal and there were no areas of anesthesia or paresthesia.

Urinary tract radiographs showed kidney shadows of essentially normal size, configuration and position and no abnormality in other respects.

Urination was normal, the stream being of good size and force. There was no residual urine.

The skin about the genital region and inner aspects of the thighs was moist and slightly reddened. Careful inspection of the vulva and introitus disclosed no abnormality except wetness of the surfaces. The source of the moisture was not evident. The external urethral meatus was in normal position and of normal appearance. The urethra felt quite normal to palpation against the pubic arch. Para-urethral gland duct openings were present but each would admit a fine probe only a few millimeters. The vestibule and margins of the introitus were carefully searched with a fine probe but no abnormal opening could be found.

On bimanual pelvic examination a normal cervix, a freely movable uterine fundus in normal position, and normal adnexal regions were found. In the right lateral vaginal wall extending downward from the fornix was a flap-like ridge of vaginal wall. This structure became less prominent toward its lower end and disappeared altogether two or three centimeters from the introitus. With the patient in the knee chest position the vagina filled well with air permitting careful and complete examination of its whole interior. The cervix appeared normal. It was wiped dry and watched for several minutes. No fluid appeared at the os. The vaginal surfaces were searched with a probe, particularly the flap-like ridge on the right wall, but no opening was discovered.

On urethro-cystoscopic examination no anomalous ureteral meatus could be found in the urethra. The bladder neck and sphincter margin were normal. The bladder mucosa and contour were normal throughout. Both ureteral orifices were present, in normal position and were normal in appearance. Indigo-carmine, given intravenously, appeared promptly and in good concentration in each ureteral jet.

It was determined to let this temporarily conclude the examination.

*Case Presentation before the Minnesota Academy of Medicine, St. Paul, Dec. 11, 1929.

Upon removal of the cystoscope the vestibule was sponged dry and re-inspected. Suddenly the mucosa just to the right of the urethral meatus became wet. Grossly, no opening indicating the source of the fluid was evident. However, a fine urethral catheter, used to probe the region, finally slipped into a minute opening. It was situated on the vestibule one-half centimeter to the right of the urethral meatus. The catheter was passed into the opening twenty centimeters. A radiograph made later showed the catheter to extend upward parallel to the position of the vagina. In the region of the bladder the catheter was coiled up in a space extending upward and to the right. The catheter could now be felt beneath the flap-like ridge in the right vaginal wall.

The cystoscope was re-inserted and a shadowgraph catheter was passed for the full length into the normal right ureteral orifice. The radiograph showed this catheter to occupy a normal position of a right ureter (Fig. 1).

The small catheter which had been introduced into the opening in the vestibule near the urethra was now injected with sodium iodide solution. The radiograph made following this (Fig. 2) showed it to outline very well a tract extending upward parallel to the vagina and a cavity in the region of the bladder in which the catheter was coiled up. Extending upward from this, the solution outlined a long narrow tract in the position of a right ureter and ended in the upper renal area in a bulb-like extension, characteristic of the high lying, rudimentary upper pelvis of a duplicated kidney. The catheter which had been passed into the normally placed right ureteral orifice within the bladder was now injected and another radiograph was made (Fig. 3). It showed this ureter well filled, of normal position and communicating with the lower pelvis of the duplicated kidney.

Fig. 1

Fig. 2

Fig. 3

The condition demonstrated was: Complete duplication of the right upper urinary tract with anomalous extra-vesical origin in the vestibule of the ureter draining the upper pelvis.

This condition represents an anomaly of the upper urinary tract—in fact, two anomalies: (1) the complete duplication of pelvis and ureter due to an anomalous cleavage of the ureteral bud; (2) the extra-vesical termination of one ureter in the vestibule due to an anomalous persistence of the attachment of the ureter to the Wolffian duct permitting the ureteral orifice to be carried down with the downward shifting duct, so that either it comes to have finally its own separate opening on the surface or remains attached to the vestigial remnant of the Wolffian duct, Gartner's duct, and reaches the surface through this channel.

Anomalies of the upper urinary tract have been classified as anomalies of form, of number and of position. Such classification seemed to me purely arbitrary and without foundation in em-

bryology. Some time ago I submitted a new classification based upon the facts of embryology concerning the morphogenesis of these malformations.

CLASSIFICATION OF UPPER URINARY TRACT ANOMALIES

- KIDNEY (*Renal Blastema*)
  - Position
    - Under-rotation
    - Over-rotation
    - Ectopia
    - Incident to Malformation
  - Form
    - Fusion
      - Horseshoe
      - Tandem
      - Lump
    - Infantile
    - Absent
    - Polycystic?
- URETER AND PELVIS (*Wolffian Duct*)
  - Cleavage
    - Partial Duplication
    - Complete Duplication
  - Origin
    - In Bladder
    - In Urethra
    - In Genital Tract
    - In Vestibule
    - In Rectum
  - Structure (Narrowing)
    - Calyx
    - Ureter
    - Uretero-Vesical Orifice
- BLOOD VESSELS
  - Division
  - Number

According to this classification anomalies of the upper urinary tract have been grouped as:

1. Anomalies of the secreting structure, the kidney proper, derived from the renal blastema.
2. Anomalies of the excreting structure, the ureter, pelvis, calyces and collecting tubules, derived from the Wolffian duct.
3. Anomalies of the renal vascularization.

The first group, anomalies of the kidney proper, result from faulty development in the renal blastema and from abnormality in the ascent and rotation of the kidney derived from this structure. The anomalies of form, such as horseshoe kidney, lump kidney and possibly polycystic kidney, and anomalies of position, such as ectopic kidney and under-rotated or over-rotated kidney of the old classification, fall into this group.

The second group, anomalies of the ureter, pelvis and calyces, result from faulty development in the ureteral bud arising from the Wolffian duct. The "anomalies of number" of the old classification, frequently spoken of as duplicated kidneys, fall into this group under the heading "cleavage anomalies." These are due to premature cleavage of a single ureteral bud or the formation of two buds.

Anomalous origin of the ureter was not taken into account under the old classification. Such anomalies are due to failure of the ureteral bud stalk to be dropped off in its normal definitive position in the bladder. Instead its attachment to the Wolffian duct persists abnormally long or permanently and permits it to shift downward with the Wolffian duct to open below the level of the bladder. This occurrence provides opportunity for origin of the ureter in the urethra in both sexes, in the common ejaculatory duct of the male or in Gartner's duct, or in the vestibule of the female. When it is combined with other departures from normal, it may give rise to origin of the ureter in the rectum of either sex, in the seminal vesicle or vas deferens in the male and to origin in the fallopian tube, uterus or vagina in the female.

Abnormal structure in the form of narrowings of the excreting channels developed from the ureteral bud gives rise to congenital strictures. They may affect the excreting channels anywhere from a calyx within the kidney to the ureteral opening in the bladder mucosa. They have been grouped under "structure."

The third group, anomalies of the renal blood vessels, occur as abnormal divisions and distributions of an otherwise normal renal artery or vein or as supernumerary vessels originating from aorta or cava or other neighboring vessels.

In the case reported, the cleavage anomaly, consisting in complete duplication of pelvis and ureter, obviously is due either to two ureteral buds having formed on the Wolffian duct or to the premature division of a single ureteral bud.

Under normal development, that portion of the Wolffian duct between its opening into the bladder or cloaca and the point of origin of the ureteral bud, spreads into the expanding bladder wall until the stalk of the ureteral bud is reached. The latter then shifts onto the bladder as a separate opening, its definitive position in the bladder being thus established. The expanding bladder

wall carries this ureteral opening lateralwards, and upwards relative to the now separate Wolffian duct opening in the bladder. In addition there is a medial, and downward shifting of the latter opening which further contributes to this relative position of the ureteral orifice and the continuing attachment of the Wolffian duct to the bladder.

Should there have been two ureteral buds, the stalk of the first one, the lower one, will first meet the bladder and shift onto it as the ureteral opening of the lower pelvis. The second stalk continuing its attachment to the Wolffian duct usually meets and shifts to the bladder before the duct attachment is below the position of the vesical neck. This stalk, representing the ureter of the upper pelvis, however, will have been carried by the Wolffian duct into a position more medial and lower than the opening of the ureter of the lower pelvis. Thus it is that the lower medial ureteral orifice in the bladder of a complete duplication, drains the upper pelvis, while the upper lateral orifice drains the lower pelvis.

In the case of a complete duplication arising from the premature cleavage of a single ureteral bud instead of from two buds, it must be presumed that the stalk of the ureteral bud either alone, after shifting to the bladder as a separate opening, or together with the Wolffian duct before this occurs, goes through this same process of spreading into the expanding bladder wall until the point of ureteral bifurcation meets the bladder wall, whereupon, in succession, first one and then the other division of the ureter will shift to the bladder as separate openings.

In the case reported, the anomaly of origin of the ureter, extravesically in the vestibule, is due to the upper ureteral bud stalk (if there were two ureteral buds) or the upper division of a bifurcated stalk (if there was premature cleavage of a single ureteral bud) failing to shift to the bladder as a separate opening, as did the ureter of the lower pelvis. Instead its attachment to the Wolffian duct either persists abnormally long or is permanent. In the first case it would represent a downward carriage by the Wolffian duct of maximal extent to the vestibule, finally shifting to this site as a separate opening. In the second case it would represent a permanent attachment of ureter to Wolffian duct which reaches the surface via the vestigial remnant of this duct as a patent Gartner's duct.

The case reported presents a unique surgical problem peculiar to such conditions. In cleavage anomalies of the upper urinary tract there may be no symptoms and no associated pathologic change. Under these circumstances there is no indication for treatment, surgical or otherwise.

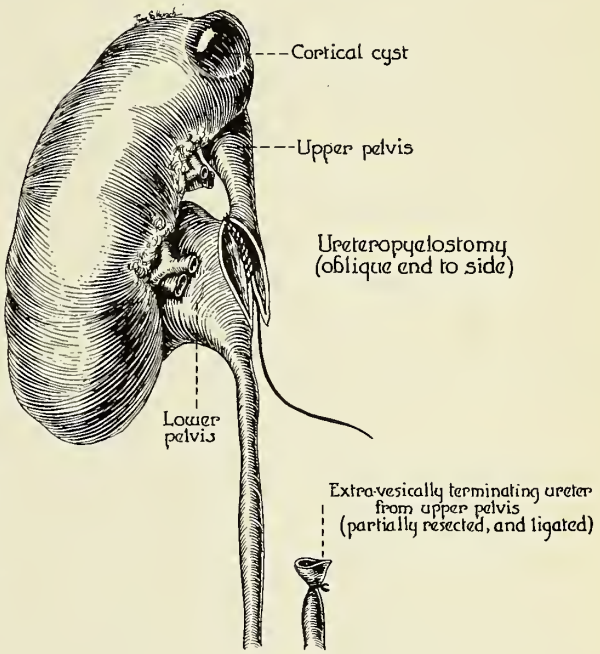

Fig. 4

Frequently, however, the anomaly is present in association with an obstructive lesion and there may be dilatation, persisting infection or stone formation, or tuberculosis or neoplasm may be present. Under these circumstances the problem of surgical treatment is rendered unique and peculiar because of the associated anomaly. In general, the major surgical procedures which come up for consideration are, nephrectomy, hemi-nephrectomy and finally the possibility of anastomosis between the two divisions of the double kidney.

Anastomosis between the two divisions is useful as applied to obstructive lesions affecting one division of a duplicated upper urinary tract, the anastomosis providing drainage for the obstructed division through the ureter of the unobstructed division.

By hemi-nephrectomy it may be possible to remove the diseased half of the double kidney, thus preserving the function of the undiseased half. In my own experience, hemi-nephrectomy has been employed four times, in all cases with

an excellent functional result. In a fifth case, hemi-nephrectomy was undertaken but because of the particular vascular arrangement and the extensive changes of a suppurative calcareous pyonephrosis involving the lower division of the kidney, the procedure had to be abandoned in favor of complete nephrectomy. The experience with hemi-nephrectomy which has been mentioned is a particularly fortunate one and such results with the procedure cannot be regularly expected. It has many undesirable features, among which may be mentioned great technical difficulty because of the particular vascular arrangement, the danger of immediate or secondary hemorrhage from the sutured cut surface of the remaining portion of kidney and urinary fistula or chronic recurring accumulations in the wound due to remaining portions of the parenchyma which had drained into the removed pelvis.

Anastomosis between the two divisions of the duplicated upper urinary tract avoids the dangers of hemi-nephrectomy, and when conditions are suitable for its employment it is a much more desirable procedure than hemi-nephrectomy. My first operation of this sort was employed more or less as a makeshift means out of a technical difficulty. The result was excellent. My first impression that this was the first operation of the kind to have been employed was incorrect. A year or so following this first operation the same procedure was carried out in a second case with an equally satisfactory result.

In the case reported, relief of the persistent extra-vesical drainage of urine might be accomplished in various ways: total nephrectomy, hemi-nephrectomy, simple ligation of the anomalous ureter, transplantation of the anomalous ureter into the bladder, or by uretero-ureterostomy or uretero-pyelostomy between the two divisions of the duplicated upper urinary tract.

Certainly in this case the lower half of the kidney is well worth saving and conservatism contra-indicates total nephrectomy. Although the upper division is of very little functional importance its removal by hemi-nephrectomy is not indicated because of any pathologic change apart from the extra-vesical opening of its ureter. This undesirable functional procedure should not be undertaken because of the extra-vesical drainage, if this can be corrected by a safer procedure assuring an equally satisfactory functional result. Simple ligation of a ureter without removal of the secreting parenchyma which it drains may be employed as has been done when the ureter is inadvertently cut during hysterectomy. If the kidney is uninfected and complete atrophy promptly results from the complete obstruction of ligation, a favorable result may be expected. On the other hand, particularly in the presence of infection, serious difficulties may ensue. Transplantation of the ureter into the bladder is a technically difficult procedure and does not regularly give a good functional result, devoid of possible complications. The exposure is difficult and transplanting the ureter so as to provide a competent uretero-vesical valve is not easy. A uretero-vesical anastomosis which does not provide against intra-vesical pressure being conducted into the ureter assures damage to the kidney above and provides an excellent probability for ascending infection and complications of real consequence.

The above considerations indicate transplantation of the anomalous ureter into the lower pelvis or ureter as the operation of choice in the case reported. Accordingly uretero-pyelostomy as illustrated (Fig. 4) was performed. The segment of ureter between the point of anastomosis and the brim of the bony pelvis was resected.

The patient made an uneventful convalescence and now more than three months since operation she remains entirely relieved of her distressing symptoms without any pain referable to this upper urinary tract or urinary disturbance of any sort and in all respects is quite well.

CORONARY OCCLUSION WITH SURVIVAL*

James A. Evans, A.M., M.D.
La Crosse, Wisconsin

CORONARY occlusion is most often a dramatic cause of fatality, but that many cases do survive is becoming more universally recognized as the clinical picture is becoming more familiar. Herrick[1] recognized this fact as far back as 1919 when he classified coronary thrombosis cases as follows:

1. Cases of instantaneous death in which there is no death struggle.
2. Cases of death within a few minutes or hours after obstruction.
3. Cases of severity in which death is delayed for several hours, days or months, or recovery occurs.
4. A group that may be assumed to exist embracing cases with mild symptoms; for example, a slight precordial pain ordinarily not recognized as due to obstruction in the smallest branches of the coronary arteries.

Only three articles, in the enormous amount of literature which has recently sprung up on coronary occlusion, have been devoted entirely to the consideration of these milder cases with recovery.

Luten[2] reported three cases in 1927 which survived one year five months, one year six months; and one year, ten months, respectively.

Levine,[3] in 1925, reported five cases with survival to the time of writing of from eight months to one year ten months.

Pardee[4] reported one case living up to time of publication in 1927, three years and three months.

Hamburger,[5] in an article not devoted exclusively to cases with recovery, reports he has seen several cases that have led fairly active lives for a period of five years or longer, giving no specific figures.

Willius[6] makes a statement that one-half the cases of coronary occlusion die immediately, and one-half survive a few days to months, or even years.

The reason for survival lies in the fact that only a small vessel may become occluded and, therefore, only a small area of heart muscle be infarcted; or, granted that a large area be infarcted, the capillary anastomoses are capable of establishing a collateral circulation to maintain nourishment to prevent a fatal thinning, scarring and final rupture of the ventricular wall. Indeed, such a rupture is sometimes the late result of an old infarction from which the patient may have survived a considerable length of time.

Wearn[7] has demonstrated beautifully the capillary bed of the heart and anastomoses formerly thought to be non-existent in the coronary circulation (Fig. 1).

A brief review of the clinical picture of coronary occlusion is presented below:

SYMPTOMS OF CORONARY OCCLUSION

Subjective

Often history of preceding attacks of true angina pectoris with normal electrocardiogram and no nitrite relief.

Terrible agonizing pain in precordium radiating down left arm.

No relief from nitrites or morphine.

Fear of impending death.

Vise-like choking feeling.

Objective

Age over 55.

Patient in shock.

Cold, clammy forehead and extremities.

Irregular rapid pulse.

Change in heart tones.

Murmurs, later pericardial friction rub.

Fever.

Slight leukocytosis.

Low blood pressure.

Pulmonary signs.

Changes in electrocardiogram.

The electrocardiograph affords the best confirmatory evidence when the so-called Pardee's phenomenon[8] is present. This change occurred in seven of our ten cases. Other suggestive changes, especially if known not to exist before, were: auricular fibrillation (1

*Presented before the Southern Minnesota Medical Association, Winona, Minnesota, June 15, 1929.

case), bundle branch block (2 cases), slurring or notching of QRS complexes (1 case).

Pardee has called attention to a fairly characteristic electrocardiographic sign illustrated in some of these curves. The S-T takes off the R-wave in one or perhaps two of the leads above or below the iso-electric point and is convex upward to curve downward into a negative T-wave. When found, this sign is very suggestive but does not occur in all cases. Wearn[9] concludes: "It is obvious there is no one form of the electrocardiogram characteristic of this condition." Only one out of ten cases reported by him had Pardee's typical sign. Clark and Smith[10] state: "No alteration of the T-waves in coronary thrombosis has been accepted by the many writers as characteristic. For clinical purposes this change consisting of elevation of the T-wave which branches from the R or S limb may be considered as strong presumptive evidence of coronary occlusion." Fred M. Smith[11] showed the electrocardiogram of a dog with typical inversion of T1 and T2 with convexity of the S-T interval following ligation of the coronary arteries.

Our case reports call attention again to the frequency of coronary disease and angina pectoris in physicians—three in our small series of ten cases. Survival in our longest case so far has been five years and two months, and this patient subsequently died of cerebral hemorrhage. Seven of the cases have so far survived more than two years, and nine of the ten cases more than one year.

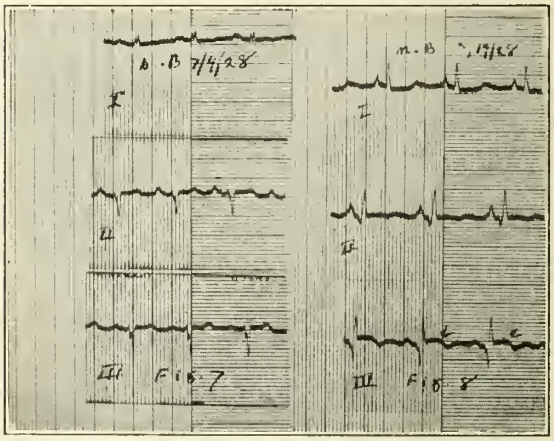

Fig. 6 Fig. 7

CASE REPORTS

Case 1.—Dr. B., male, aged 69, experienced a mild precordial pain while hunting. His electrocardiographic tracing was normal (Fig. 2) the morning of the same day infarction occurred. That night, and for the next week, he presented all the classical signs of coronary infarction enumerated earlier in this article. Four days after infarction TI had become flat (Fig. 3), but

not until twelve days after occlusion did Pardee's phenomenon occur (Fig. 4).

Note in Figure 4 that S-TI is above the iso-electric line and TI has become negative with the S-T interval convex upward. Two months later the patient had resumed normal activity. The tracing then showed (Fig 5) improvement in an upright T2. A year after infarction (Fig. 6), Pardee's phenomenon has disappeared, but TI is still flat. He has no more pain but a tendency toward congestive heart failure when too active.

Fig. 14

Fig. 11

Fig. 12

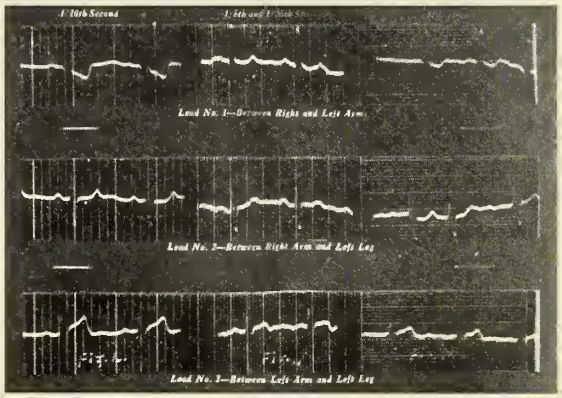

Fig. 15

Fig. 16

Fig. 17

Case 2.—Angina is notably absent in congestive failure as shown by our second case, a woman of sixty-four, who died two years after her occlusion with pulmonary edema and general anasarca. She had repeated attacks of angina till congestive failure set in, with Pardee's sign in the electrocardiogram (Fig. 7). After that, she was free from pain till compensation was restored, when attacks of precordial pain recurred. Subsequently, a second and final period of decompensation brought relief from pain.

Hamburger[5] indeed reported three patients who suffered but very little pain but died of congestive myocardial failure based on coronary occlusion. In these cases the occlusion may be very gradual.

Case 3.—L. M., a female aged 62, had had gradually increasing dyspnea for two weeks previous to falling in a faint two days before the electrocardiogram was taken. No history of cardiac pain could be elicited. Physically she had marked cardiac hypertrophy, a palpable liver edge, sacral edema, orthopnea, cyanosis and blood pressure of 86 systolic and 54 diastolic. The white count was 9,600, the temperature 102. She also had a stone in her left kidney pelvis and pyuria. She was discharged five weeks later in a good state of compensation and, as far as we know, is in fair health three and a half months later. She illustrates a painless type of infarction in whom the diagnosis could only be guessed without electrocardiographic confirmation demonstrating Pardee's phenomenon (Fig. 8).

Case 4.—John M., a male aged 59, suffered from very severe precordial pain for five days with fever, rapid pulse and collapse. A precordial friction rub developed. The electrocardiogram was taken one year after infarction and still showed Pardee's phenomenon in the second and third leads (Fig. 9). He is in good health two years and five months later.

Case 5.—Dr. D., a male aged 62, dated his limitation of activities, due to precordial distress, to a single severe protracted attack of angina pectoris two years before this tracing was taken. Lead I shows Pardee's phenomenon (Fig. 10). His survival so far has been two years nine months.

Case 6.—F. M., a male aged 67, had his first attack of

angina pectoris four and one-half years ago. In February and July of 1924 his electrocardiogram showed a negative TI at another clinic. In January and July, 1925, his tracings were reported practically normal. After freedom from symptoms for three years a Pardee's sign was present in his electrocardiogram four days after a severe second attack (Fig. 11). Two and a half months later there was only a negative TI and Pardee's sign has disappeared (Fig. 12). He is alive and working, free from further attacks four and one-half years after his first infarction and one and three-fourths years after his second attack.

Case 7.—W. M., a male aged 54, suffered a very severe attack of precordial pain accompanied by an irregular pulse, temperature of 99.8, and had a white cell count of 14,150. He had had an old luetic infection which had been treated and now has a negative Wassermann. Two days after his infarction he had a flat TI and numerous extrasystoles (Fig. 13). Three months later the TI was again positive but Pardee's

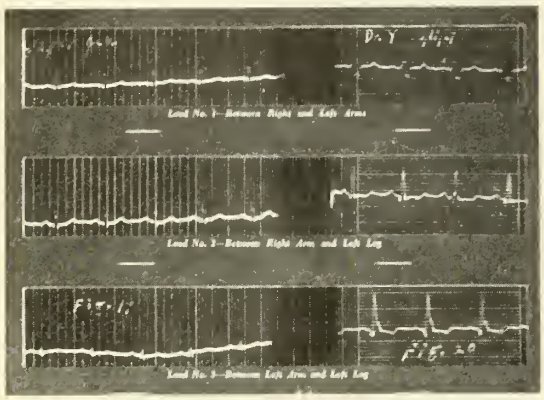

Fig. 18

Fig. 19

phenomenon was present in Leads II and III (Fig. 14). He is an active insurance agent one and one-half years later.

Case 8.—J. W. G., a male aged 68, had had repeated typical attacks of angina pectoris for the past eight years before his first electrocardiogram was taken, which showed a right bundle block (Fig. 15). Six months later, during which interval he was free from attacks, a second tracing showed the bundle branch block had disappeared (Fig. 16). A third tracing four and one-half months later, about two months after a severe attack of angina, then showed the bundle branch block had reappeared and, in addition, an auricular fibrillation (Fig. 17). This patient also had gallstones and a diverticulum of the esophagus. He is still living a fairly active life one year after his last infarction, free of angina with good compensation under digitalis.

Case 9.—Joe M., aged 64, had an infarction two and one-half years ago, accompanied by severe precordial pain, vomiting and hemoptysis. The attack was followed by left basal pulmonary infarction, and, later, signs of embolism in the left posterior tibial artery and fresh pulmonary infarctions. The diagnosis was infarction of interventricular septum due to occlusion of the descending branch of the left coronary artery with mural thrombus on both sides of the septum, casting off emboli to both the pulmonary and systemic circulations. The tracing was taken one month after infarction and showed no abnormality of the T-waves, and only a slurring and notching of the QRS complexes in Leads II and III with low voltage (Fig. 18). This man's activities are limited by dyspnea and precordial pain, two and one-half years after infarction.

Case 10.—Dr. Y., male, aged 66. Five years before this patient's tracing was taken he had an attack of angina pectoris diagnosed coronary infarction. He led a very active country practitioner's life ever since without any distress. At the date of this curve, he was suffering from thrombo-angiitis obliterans. There were also signs of arteriosclerotic kidneys, marked peripheral arteriosclerosis, and two months after this tracing he died of cerebral hemorrhage. This case illustrates the effects of universal vascular disease. The electrocardiogram shows a left bundle branch block (Fig. 19). He survived his coronary occlusion five years and two months to die other than a cardiac death.

CONCLUSIONS

1. Ten cases of coronary occlusion are reported with survival—the longest duration being five years two months. Two of these cases survived at least two occlusions besides having attacks of angina pectoris.

2. The electrocardiogram offers substantial corroborative evidence of coronary occlusion, and, of the changes found, Pardee's sign is the most suggestive (seven out of ten cases).

3. Pardee's sign was found to appear as early as the second day and to still be present, in some cases, as long as two years after occlusion took place.

4. Many cases survive minor occlusions, and rare cases extensive infarcts.

5. Death may occur in these cases months later from congestive myocardial failure with or without further attacks of precordial pain.

DISCUSSION

Dr. C. N. Hensel (St. Paul): The problem of coronary infarction and its relation to the subsequent viability of the patient has been beautifully presented to you today. It is an interesting fact that these cases of proved infarction can survive such an insult to the heart provided the condition is recognized at the onset and the treatment guided by both clinical and electrocardiographic findings. This characteristic cresentic shaped deflection of the T-wave is the best diagnostic criterium and the cases that recover may show a return to the normal contour.

This problem of coronary infarction is not only of interest to the internist but also to the surgeon. Frequently in cases of coronary infarction, the pain originates in the abdomen, only secondarily rising to the lower sternum, and may cause symptoms simulating acute abdominal disease such as gallstone colic. Cardiograms in these cases may show the characteristic changes in the T-wave and thus forewarn of grave cardiac condition and perhaps cause postponement of surgical intervention.

I recall one such case of a woman of seventy years of age who had had repeated attacks of gallstone colic for many years. The present attack was of undue severity and attended with more than the usual prostration. She was taken to the hospital and watched for twelve hours under the exclusive care of a very competent surgeon. There was tenderness over the gallbladder region, muscular rigidity and pain over the lower part of the sternum. Slight fever and leukocytosis were found. At operation a gallbladder full of stones was found but because of her poor general condition and of a rapid pulse the operation was quickly terminated, the gallbladder being left in place and drainage instituted. When seen at six o'clock that evening by her attending physician her condition seemed to be satisfactory. At twelve she awakened from a drowsy sleep gave a few gasps and was dead. At autopsy the pericardial cavity was found filled with blood. When the heart was removed one could detect an area of softening in the wall of the left ventricle in which there was a small tear entirely through the wall. It was from this torn area that the hemorrhage took place, which caused her death. The microscope revealed that this area of softening was due to a previous coronary infarction and undoubtedly this infarction was responsible for her pain simulating her gallbladder attacks. It seemed probable that the strain of the operation and the subsequent nausea had been sufficient to rupture the heart. Had an electrocardiogram been made previous to operation it might have warned the surgeon of the serious damage to the heart and the fatal issue might have thus been avoided.

Since we have been using the electrocardiograph more routinely we have come to recognize that there are patients who have the angina pectoris syndrome without coronary infarction, but who eventually develop infarction of tiny branches of the coronary arteries, accounting for the more prolonged attacks of anginal pain. In these cases usually the final major attack of pain will cause the death of the patient and at autopsy multiple areas of fibrosis in the heart muscle are found, indicating previous infarctions. So the electrocardiogram is frequently of value in differentiating simple angina pectoris from mild coronary infarction.

I have a case to report with a few lantern slides which illustrates Pardee's phenomenon in the T-wave that Dr. Evans has shown through his series. The patient, a Jewess, fifty-six years of age, a diabetic for five years, was seized suddenly after a hearty evening meal with intense pain in the middle of the sternum. My associate was called and found a bounding pulse and strong heart tones. Blood pressure was 220 systolic and 110 diastolic. Surrounded by anxious relatives and greatly excited herself, it was difficult to be sure that the patient was really ill. Nitrites and morphine brought some drop in blood pressure and some relief of the acute pain, but a dull sternal pain persisted for several days. An electrocardiogram the following day showed a slight coronary T-wave in Lead 1 with a deeper drop on the second day, subsequent records showing a gradually rising T-wave till at the end of three weeks the T-wave had lost its coronary curve and was only slightly flattened in Lead I.

The patient has now lived a year and a half following this attack of coronary infarction. Of course we know that diabetic patients have as a rule a generalized arteriosclerosis and are susceptible to coronary infarction. This case illustrates nicely what happens with recovery. I have had experiences with other cases illustrating the same points Dr. Evans has shown. Some of them make clinical recoveries, others do not die, but they drag around with a persistence of marked debility and greatly limited heart capacity. The cases that recover their former energy show eventually a return of the T-wave to the upright position. The cases that do not recover their customary energy usually show on their cardiographic records a persistence of the downward declination of the T-wave or a marked flattening of the T-wave, indicating grave myocardial damage.

The cardiograph is becoming of increased value as an aid to differential diagnosis, and as a guide to treatment.

Dr. George Eusterman (Rochester): I want to bring out two points. The other day I had a patient

who had been with us seven years previously and we had made a diagnosis of generalized arteriosclerosis. He came back presenting gastro-intestinal disturbance, largely gastric. No evidence of disease of the gastro-intestinal tract or biliary tract was found. There was a little history of dyspnea. The heart was of normal size and normal rhythm. There was evidence of some torsion of arch of the aorta on the film. Generalized arteriosclerosis was present as before. The blood pressure was normal. The patient was reassured that there was no organic gastric disease. Two weeks later the brother wrote that after a hearty dinner the patient went out and played golf, and died suddenly on the course.

Willius says that practically 50 per cent of those with infarction of the coronery arteries die in the first attack.

One other point is the sensitivity of the patient with angina pectoris and coronary infarction. Libman brought this out at the meeting of the Association of American Physicians. Dr. Evans brought out the point of the degree of pain. Libman feels that patients vary in sensitivity to pain and that insensitive patients may have definite infarction without any pain; he demonstrated this point in three or four patients in the wards at Mt. Sinai, using pressure on the styloid process as the index. Crohn feels that patients whose first symptoms of gastric disease are hemorrhage or perforation or obstruction are insensitive persons who do not have the usual symptoms. The same is true of patients with cancer who go on to inoperability before symptoms occur. I want to congratulate both Dr. Evans on his presentation and Dr. Hensel on his discussion.

JAUNDICE PROBLEMS*

S. H. Boyer, M.D.
Duluth, Minnesota

JAUNDICE, the symptom, is forever flashing itself before us. Sometimes it is thought of as something likely to appear during the course of a disease under observation and then it does not surprise us when it comes, but more often it appears unexpectedly as a seemingly isolated sign. It always rouses curiosity and is always a puzzle. Wonder as to its cause, query as to its treatment rise up like a blank wall. There is a feeling akin to helplessness. I suppose almost every doctor has had that experience.

Of course the various etiological factors pass before one's mental vision, but, even so, diagnosis is not always so easy. Besides, there are cases that do not permit of a thorough clinico-scientific study. The patient may refuse special methods of examination, may be unfit to bear such methods, may be remote from a place where such technical work is available and may refuse to be moved; also, the patient's history may be difficult or impossible to secure. All these and perhaps other factors make it necessary for the doctor to know the clinical picture of the various conditions presenting the common symptom of jaundice and to be able to thread his way through the diagnostic labyrinth with a minimum of special technical methods. An aged person presents jaundice as a salient symptom and the most careful analysis of recognizable concomitant symptoms may fail to enable us to say whether there be duct obstruction due to pressure from outside, changes within the walls of the duct, obstruction from within the lumen or changes in the liver substance or perhaps a jaundice of hemic origin. If surgery or autopsy be not done etiological diagnosis may never be made.

A few actual cases will be discussed, as that is the best way to draw parallels and contrasts.

Case 1.—A woman thirty-eight years of age and the mother of several children said she had been quite well up to two months prior to admission to the hospital. She then began to feel tired and indisposed, lost her appetite, felt nauseated much of the time and occasionally vomited. She presents a Grade 1 icterus and admits upon close questioning that she first noticed this some three months ago, characterized by periodicity, a gnawing pain in the stomach at a variable time after meals and relieved by food. She has never had an acute attack of pain. Continuing to question searchingly it is learned that she has had much indigestion over a period of many years and also alternating constipation and diarrhea. She states that her indigestion is better than it was, that it has varied in degree and that her stools have been and are a pale yellow. Her physician says the urine contains bile.

What is the etiological factor in this case? So-called acute catarrhal jaundice must be thought of but the variability of her icterus, its long duration, absence of fever together with her gastro-intestinal symptoms are certainly suggestive of chronic cholecystitis and secondary irritation of the colon. Perhaps a stone shifting its position between the cystic and common ducts would account for the variable jaundice. The patient was too ill to be subjected to a complete gastro-intestinal and Cole-Graham examination at the time. However, the Van den Bergh tests and blood count were done. The results both complicated and clarified the diagnosis. They were as follows:

Icterus index, 20.

Van den Bergh (direct) negative.

Van den Bergh (indirect) immediate and positive.

Blood picture: that of pernicious anemia.

Treated with liver extract her improvement was prompt and rapid.

The blood picture and indirect Van den Bergh would indicate icterus of hemolytic origin and made a different interpretation of the gastro-intestinal symptoms possible. But, why the pale stools? Certainly we do not expect such in pernicious anemia. May not cholecystitis also be present? At a later date when the patient's condition permitted, the Cole-Graham examination was made. Dr. T. G. Clement, roentgenologist, submitted the following report:

"G. B. not filled in 12 and 15 hours but well filled in 24 hours.

"Small dense shadow cystic duct suggesting stone. Delay in filling and emptying time of gallbladder suggests and confirms cystic duct ob-

*Presented at the annual meeting of the Northern Minnesota Medical Association, Bemidji, Minn., Sept. 2, 1929.

struction." Here then is a case for multiple diagnosis—clinically the gallbladder symptoms masked those of pernicious anemia. The latter was not accompanied by nerve symptoms in this case. The positive Van den Bergh indirect test pointed away from duct obstruction and when supplemented by the blood examination the source of the jaundice became clear. It was of hemolytic origin. The long years of gastro-intestinal symptoms surely antedated the onset of the pernicious anemia. They were characteristic of gallbladder disease. The *x*-ray examination tends to confirm that diagnosis.

Case 2.—A white female, aged 25, married, was taken ill with headache, weakness, vertigo, nausea and vomiting. Then came labor pains, convulsions and coma. Labor was precipitate. She was then taken to the hospital, two days after the beginning of her symptoms. She was still unconscious and icterus was noticed for the first time. It was about Grade III. The record shows her to be poorly developed and poorly nourished, to have a badly neglected mouth, a normal blood pressure, impalpable spleen and liver, no edema. Other physical findings were essentially normal. The vomitus had been clear and watery at first but was coffee ground type when admitted to hospital March 15. It continued so for the next two days, by which time she had regained consciousness, felt languid and nauseated, but otherwise quite comfortable. Shortly the icterus was complicated with fever.

It may be assumed that a toxemia of pregnancy had existed and was subsiding, but what about the jaundice? Again the puzzle. Was it acute catarrhal jaundice or acute yellow atrophy? The languor, continued mental dullness and fever were not distinctive. They could be attributed to the recent eclamptic state. The fever could be attributed to a poorly contracted and poorly involuting uterus. It could be associated with an acute cholangitis. It could be accounted for by an acute hepatic degeneration. The latter is common enough in pregnancy to not excite surprise when it occurs. Admittedly it was too early to arrive at a definite diagnosis. Laboratory methods might help, but in their absence, and conceivably with them, time alone could solve the problem.

On the first, second and third days after admission her icterus index was 85, 89, and 187 per cent. On March 21, 8 days after admission, the Van den Bergh direct was four plus and the indirect was the same. The test for urobilin in the urine was negative. The ammonia nitrogen urinary output on March 19, 20, and 21 was 2.2 gm., 1.3 gm. and 0.5 gm., respectively. The blood examination on March 16 (next day after admission) was 78 per cent hemoglobin, 4,620,000 erythrocytes and 22,200 white cells. The next day the white cell count was 27,400.

Now, how may we interpret the laboratory reports to aid us in reaching a rational conclusion? It is true that acute yellow atrophy may be accompanied by headache, coma, and convulsions, but these do not precede the icterus, they follow it, and appear late in the affection. Thus we may be sure that in this case they were probably due to a pregnancy toxemia and that whatever may have happened to the liver in the way of acute degeneration, even though due to the same primary etiology, was of later development.

The laboratory findings of a high and rising white cell count point clearly enough to infection, sufficient perhaps to start degenerative hepatic changes. But a high leukocytosis is not in itself distinctive of acute yellow atrophy. The rising icterus index is common to all forms of obstructive jaundice and taken alone is not etiologically distinctive. The Van den Bergh tests, direct and indirect, are high. Again we find nothing definitely diagnostic. We may infer from them that all the bile secreted by the liver does not reach the intestine and that some change is probably going on in the liver cells, the nature of which we do not know. It might also be inferred that some of the jaundice might be due to blood destruction. However, the near normal erythrocyte count, 4,620,000, does not justify such a conclusion. The negative urinary urobilin findings also point away from hemolytic jaundice. If bile reaches the intestine it is in part converted into urobilinogen and urobilin. As such it is reabsorbed, taken to the liver and converted into bilirubin. If the liver is so badly degenerated that it cannot change urobilin into bilirubin it is probably also incapable of secreting bile; therefore urobilin would not be expected to appear in the urine in acute yellow atrophy. As the net result is the same in complete obstructive jaundice the failure to find urobilinuria does not help us much. The record fails to show the color of the feces. If an observation had been recorded indicating the presence or absence of bile in the stool, then this, taken together with icterus, would afford something tangible in the direction of an etiological diagnosis. We are denied this small help.

One function of the liver is deamidization. The laboratory record shows a marked increase in the ammonia nitrogen excreted in the urine. This is suggestive of failing liver function. As this patient had suffered a pregnancy toxemia we cannot be sure that an acidosis was not responsible for the high ammonia nitrogen excretion in the urine. The latter view is strengthened by the following rapid reduction in the ammonia

nitrogen output. Thus but little positive diagnostic aid is derived from the laboratory findings, which, by the way, are sometimes apt to be very confusing to one doing clinical work. As this patient began to improve very shortly, and was discharged from the hospital as cured at the end of two weeks, it is quite likely that the final diagnosis of acute catarrhal jaundice was correct. On the other hand we are not to assume that there was no degree of acute hepatic degeneration. The toxemias of pregnancy are known to be peculiarly causative of the syndrome mentioned. It may very well be that such a process actually started in this case but owing to the weakness of the toxemia, or its short duration, or to a high power of resistance by the patient, or all three influences together, resulted in recovery with but little damage. How little or how much damage may never be known. Perhaps the reparative scarring may be sufficient to cause symptoms of hepatic cirrhosis at some future time. Perhaps some day this patient may come to autopsy, when the pathologist will read the story of an old arrested acute yellow atrophy.

Case 3.—A male, aged 21, a laborer, sailor and world wanderer, was admitted to the hospital August 31 and died two days later. The record shows that his illness started about two weeks before entering the hospital. He felt weak, had headache and slight jaundice. A doctor sent him to bed for a week. He then worked two days and quit. There was progressive weakness and icterus, prostration, confusion, delirium and stupor —then death.

The past history and physical findings in this case are meager indeed. He was well nourished, had dental caries, icterus, and his liver and spleen were not palpable. These were the only notations of interest.

The laboratory report shows a normal blood count except for a slight leukocytosis of 10,000, an icterus index of 166, Van den Bergh negative direct and positive indirect. The diagnosis recorded is acute yellow atrophy.

Certainly this case record affords very little for purposes of scientific study. The course of the illness, however, contrasts markedly with that of the preceding case and confirms the statement that delirium, convulsions and stupor are late symptoms in acute yellow atrophy. Note that in this case the onset was gradual, the course progressive and the end fatal. Note that in the preceding case the onset was sudden, the icterus followed the convulsions, the progress was toward rapid recovery.

Now why should this apparently healthy young man develop this fatal malady following a seemingly normal condition? Certainly acute hepatic degeneration does not arise without cause. Certainly, also, dental caries as noted in the record could hardly be accepted as the probable cause. That this disease is due to an intoxication or infection of some sort there can be little doubt. Failing to find it in the clinical record we turn to the autopsy hoping for something informative. The autopsy report is submitted in brief:

Teeth are carious.

Liver weighed 1,000 gm.; is mottled with yellowish patches and softer than normal. Cut surface shows soft yellow patches alternating with purplish red patches. Bile ducts are patent. Acute cholecystitis present.

Small hemorrhages present in mesentery and kidneys.

Post-mortem diagnosis: Probably acute yellow atrophy, acute cholecystitis, dental caries, pulmonary edema, small hemorrhages into mesentary, omentum and kidneys.

On the basis of this report we can assume the mouth hygiene to have been extremely bad and accompanied with dental and gum infection. We could think of this as a possible etiological factor but acute cholecystitis should be considered in that role a great deal more logically. It could be considered more seriously if an associated cholangitis had been reported. The absence of any definite source of toxemia leaves us in the realm of speculation. One can't help but wonder if this homeless wanderer may not have been luetic, and, if so, had he been treated with antiarsenicals and been an individual sensitive to arsenic?

THE DIAGNOSIS AND TREATMENT OF ABNORMAL UTERINE BLEEDING*

Archibald L. McDonald, A.B., M.D., F.A.C.S.
Duluth, Minnesota

THIS discussion is limited to the significance of various types of pathological uterine hemorrhage and excludes that associated with late pregnancy and labor.

To appreciate the abnormal we must accept a working hypothesis of normal menstruation and pregnancy. Much research still leaves many points at issue. For practical purposes, however, we are justified in certain dogmatic assumptions based on the work of Frank and his collaborators.

1. We assume the formation of a single, specific "sex hormone" secreted in the ovary; certainly in the Graafian follicle and corpus luteum; and probably also in atretic follicles, stroma, and the so-called interstitial cells. After implantation of the fertilized ovum, this hormone is stored or formed in the decidua and placenta.

2. The relatively small amount of hormone furnished by the immature ovary, in conjunction with internal secretions of the pituitary, thyroid, adrenal, and other glands, is sufficient to determine prepubertal development of the special and secondary sexual characteristics.

3. Periodic maturation of the ovum, including development of the Graafian follicle, its rupture, and formation of the corpus luteum, all of which begin at puberty, causes recurring waves of increase in the amount of sex hormone in the body, followed by sharp decline. These cyclical variations induce equally constant changes in the uterus and endometrium, sufficient to provide a suitable field for implantation of a fertilized ovum, should it be present. In that case the corpus luteum persists for a time. From this source and from the decidua and placenta, an adequate amount of hormone is provided to maintain a status quo in ovaries and uterus to nourish and to protect the growing product of conception. It prevents uterine bleeding and probably inhibits ovulation.

In the absence of implantation, there is a sharp decline in the amount of sex hormone, associated with atrophy of the corpus luteum and bleeding from the congested endometrium. Therefore, physiological uterine bleeding, menstruation, occurs only from an endometrium altered by an increase of sex hormone associated with ovulation, and is due to a sudden decrease of this secretion in the absence of successful implantation of a fertilized ovum. A number of factors modify the duration and amount of hemorrhage. Variations in periodicity are always pathological.

Menorrhagia, excessive or prolonged menstrual bleeding, is a relatively abnormal reaction to normal stimuli. It is pathological when the blood lost is not restored during the intermenstrual period. Anemia is frequently present and indicates the severity of the condition. Following puberty some variation is common. Usually it is temporary and self limited, being of slight significance. In other instances constitutional treatment is followed by readjustment. An occasional case, however, will present serious effects and prove most baffling.

Endocrin imbalance, blood dyscrasia, and, rarely, local lesions are to be considered in the etiology. Endocrin factors include ovary, thyroid, pituitary, adrenal, possibly other glands. The disturbance is often temporary. Gland therapy is still empirical or worse, assurance of detail men to the contrary notwithstanding. Blood dyscrasia, hemophilia, and thrombocytopenic purpura are surprisingly frequent in young women. Low blood platelet counts, under 60,000, are suggestive. Chlorosis, with its characteristic blood picture, is not uncommon. These conditions are the cause of many obstinate cases of menorrhagia. Therapy with calcium, iron, or blood transfusion is most effective. Tuberculosis and lues are occasional causes of this type of bleeding.

X-ray treatment of the splenic region through its action on blood formation has some value. Effort to modify ovarian secretion by this agent, unless used with great skill together with a large measure of good luck, is likely to do more harm than good. At this period of life some type of constitutional treatment is the method of first choice. Local pathology is less common and less important than later in menstrual life. Pelvic

*Presented at the annual meeting of the Northern Minnesota Medical Association, Bemidji, Minn., Sept. 3, 1929.

examination under anesthesia is usually negative. Uterine curettage is rarely of therapeutic value. Resection of ovarian cysts or a cystic ovary may occasionally give more than temporary improvement. Hysterectomy or castration in the young is a frank confession of failure. However, one may be forced to consider it in uncontrollable cases.

The importance and frequency of local causes increase with years, with infections, and with childbearing. Tumors, local inflammation, subinvolution and prolapse—all predispose to menorrhagia. Thorough examination will reveal the cause. Properly selected surgical treatment will control the bleeding, and retain ovarian secretion. Hence it is truly conservative. In some cases of prolapse and subinvolution subtotal hysterectomy offers the most effective solution. Radiotherapy in a carefully restricted group of cases may be considered. Contraindications are: Inflammation or sepsis, ovarian tumor, large uterine tumor, submucous fibroid or polyp, cachexia or severe anemia. Malignancy must be excluded. Pregnancy must be interdicted for at least a year following treatment.

Metrorrhagia or irreguar uterine bleeding of whatever degree is an objective sign of serious import. It is independent of ovulation. It is always abnormal. The amount may vary from blood-tinged discharge to profuse and dangerous flooding. It may follow local trauma, examination, douche, or intercourse. It may be intermittent, or nearly continuous. In any case one must exhaust every means to find the cause and carry out proper treatment without delay.

We shall consider two groups.

1. Bleeding due to a pathological condition in early pregnancy.
2. Bleeding due to other local lesions.

Any bleeding during pregnancy is pathological. It may occur before there is reason to consider pregnancy. If accompanied by unilateral pain, one must suspect an ectopic implantation. So-called menstruation during gestation is due to atypical hypertrophy of the decidua which bleeds easily in response to variations of the sex hormone. This bleeding is periodic in type, slight in amount, unaccompanied by pain. It is quite different from that associated with placental separation or threatened abortion. Thyroid extract is of definite value.

Impending or actual abortion with disturbance in placental attachment is the most frequent cause of uterine bleeding during early pregnancy. In such cases one must consider several questions:

1. Is the abortion only threatened or is it inevitable? If the blood lost exceeds that of normal menstruation, or if there are severe uterine contractions, the fetus is probably dead and will be expelled. Rest and narcotics may prevent threatened cases, but do not delay an inevitable abortion.

2. Is the interruption of pregnancy spontaneous, or has it been artificially induced? In the latter case we recognize an increased liability to infection and to retention of secundines.

3. Is the abortion complete? Examination of the material expelled may give the answer. Bleeding continues till the uterus is empty. Unless this has been accomplished spontaneously within a few days or a week, mechanical assistance is necessary. Oxytoxics are uncertain but may be tried. Vaginal manipulation or packing is but little safer than proper exploration under anesthesia. It is also of slight value. Hemorrhage is the only indication for interference. It is rarely sufficiently alarming to justify emergency operation. One must allow time to exclude infection. History of previous vaginal manipulation requires extra caution. Repeated intrauterine operations should be unnecessary; they are dangerous as well as useless. An adequate procedure will control bleeding in all simple cases, or suggest the presence of other conditions. Fever means infection and contraindicates any local manipulation. Study of the curettings may disclose hydatid mole or malignancy. Negative uterine findings together with careful bimanual examination will sometimes disclose an ectopic pregnancy which is in process of abortion. The clinical picture is often confusing. Uterine bleeding begins with disturbance in placental attachment and continues till ovulation is re-established.

Aside from pregnancy, metrorrhagia is always due to local lesion with destruction of the endometrium. Its causes include:

1. Preclimacteric hypertrophy of the endometrium, in rare instances. Diagnostic curettage fails to disclose cancer. This operation, together with suitable pelvic repairs, is followed by cure. In case of recurrence the presence of cancer must be assumed and radical treatment instituted.

2. Submucous or pedunculated fibroid tumors are associated with hyperemia and destruction of the endometrium resulting in metrorrhagia. Di-

agnostic curettage and biopsy is necessary to exclude cancer which may accompany gross tumors. In its absence excision of the growth or hysterectomy is the proper procedure. Radium is not advisable.

3. Cancer involving the mucosa promptly causes intermittent bleeding. This is the earliest and most constant sign of the disease. This type of abnormal bleeding, including postclimacteric hemorrhage of any sort is an absolute indication for immediate diagnosis and treatment. Biopsy and study of curettings permit the diagnosis of cancer. If properly done it is without danger, provided therapy is instituted at once. Study of cell structure will influence prognosis and type of treatment. For cancer of the body or fundus, total hysterectomy offers a good prognosis, and is the procedure of choice. For cancer of the cervix or vaginal portion, radium, properly applied, has largely supplanted surgery, even in early operable cases. Systematic follow-up with efficient doses of deep *x*-ray is advised.

To summarize: Variation in amount or periodicity of uterine bleeding is a frequent symptom and sign. Abnormal duration or amount indicates a study of constitutional factors, after which local causes should be sought. There is comparatively slight danger from reasonable delay for investigation. Variation in the usual periodicity, however, points to local pathology. Diagnosis is urgent and is always possible. This must precede treatment. Curettings must be studied grossly and microscopically. There is no excuse for repeating a therapeutic curettage. We must emphasize to ourselves and to our patients the fact that metrorrhagia or post-climacteric bleeding is always pathological. It is only by full appreciation of this fact that we can reduce the mortality of cancer of the uterus.

Again, abnormal uterine bleeding is an important objective evidence of disease, unequivocal in character, and simple in interpretation. Let us give it the attention which it deserves.

HYPERTHYROIDISM IN CHILDREN*

Max W. Alberts, M.D.
Saint Paul

UNTIL a few years ago hyperthyroidism in children was thought to be extremely rare. Although the condition is being met with more frequently, we can still follow Helmholtz' dictum that it is extremely rare in early childhood, and becomes more common with the approach of puberty. It seems to be, however, more or less limited to the female, for I am able to find only one case in the literature of hyperthyroidism in a male child under ten years of age.

In agreement with previous articles on this subject we have chosen fourteen as the upper age limit. Although this series of eight cases is rather small, still the lessons learned in handling them have been very interesting and instructive.

REVIEW OF LITERATURE

Lewis in 1914 reported five cases of exophthalmic goiter in children among 1,512 goiter patients operated on at the Mayo Clinic between 1905 and 1913. Sattler has reported the largest series, having studied 184 cases in children among a total of 3,477. Dinsmore in 1926 reported forty-eight cases of hyperthyroidism in children observed at the Cleveland Clinic, eight being in boys and forty in girls.

Numerous single cases have been reported by various men, while White has reported a case of exophthalmic goiter in a newborn infant where the mother was suffering from the disease, and Klaus in 1914 reported a case in a nine month old infant.

ETIOLOGY

The cause of this disease is more or less uncertain. However, by reviewing the case records of the various individuals coming under my observation, I have come to some definite conclusions as to the factors which to me have been practically specific in causing a hyperactivity of this gland.

Infections.—Three of the patients in our series definitely attributed the onset of the present illness to some acute infectious disease, two of them having had influenza and one scarlet fever within two years of the time they came under observation. Many other infectious diseases such as tonsillitis, sinusitis, and pneumonia, have been reported as factors in the production of hyperthyroidism.

Shock, Injury or Emotional Disturbance.—A great deal has been written and there have been many discussions regarding the influence of bodily injury or mental shock on the activity of the thyroid gland. This discussion has been confined mostly to adult cases, and from a medico-legal point of view a great many theories have been advanced; however, very little has been said regarding this factor as a causative agent in children.

Hill reports a case, that of a seven year old girl, who, on account of some harrowing experience encountered during the war, developed a typical exophthalmic goiter.

In our series of cases, there were two which we can definitely place in this category. One patient had been slightly injured and badly frightened while on a sleigh ride. The other, a girl, had been perfectly well until the afternoon her grandmother was buried, when she suddenly became rather hysterical and began vomiting, which was followed by the typical hyperthyroid syndrome.

Use of Prophylactic Medication.—This is another phase which brings forth a great deal of discussion. So much has been written in the newspapers and lay magazines regarding the prevention of goiter that a large number of so-called preventatives have been placed on the market and given to children with absolutely no thought of putting the child under the care of a physician while the medication is being used. It is rather left to the grocer, druggist, nursemaid or mother to determine the dosage. While I believe the prophylactic use of iodine or one of its derivatives is a perfectly correct procedure when given under medical supervision, nevertheless we have seen cases of hyperactivity of the thyroid gland develop in such instances. Marine and Kimball in their series of 4,415 children who received iodine as a prophylactic had from 0.5 to 1 per

*Presented at the annual meeting of the Northern Minnesota Medical Association, Bemidji, Minn., Sept. 3, 1929.

cent of their cases develop symptoms of hyperthyroidism which promptly disappeared when the medication was stopped.

DeQuervain had a similar experience, but thinks that the risk is nil if the prophylactic dose does not exceed three milligrams.

Bram in a series of 3,343 cases saw 3 per cent develop hyperthyroidism while an additional 1 per cent had trouble from the use of thyroid extract.

By far the most dangerous prophylactic used today in my opinion is iodized salt. Three of the patients in our series gave a definite history of having used this type of salt from two to three years, and without doubt this changed an inactive goiter to a very active type.

Adolescence.—Because of the rather sudden rise in the number of cases of exophthalmic goiter about the time of puberty, the theory has been advanced that the change in the life cycle may be a factor in causing an increased thyroid activity. The great majority of cases of hyperthyroidism, as we know, occur during the period of sex life, and it is a very reasonable theory that the ovarian activity has an inter-relationship with the activity of the thyroid, and vice versa.

PATHOLOGY

The glands in this series of cases (and all were partially or totally removed save one in which a unilateral superior lobe ligation was done) showed the gland to be bilaterally enlarged, rather firm in consistency, with some areas throughout the gland which were soft and friable, evidently areas of degeneration. Such an area may often on palpation be confused with a small adenoma, which would follow Kitchen's observation on examining large groups of children having enlarged thyroids. None of these patients had true adenomas, and I am unable to find any case in the literature of hyperthyroidism with adenomas in children. In fact Plummer states that it is an exceedingly rare observation in persons under the age of twenty-five years.

The microscopic picture was somewhat varied in that certain portions of the glands showed a true hyperthyroid state with cells of the columnar type, some of which were undergoing mitosis, with the acini small, and filled with a rather small amount of thin material. On the other hand portions of the gland gave the appearance of being inactive with the cells flattened, the acini distended with colloid and a marked decrease in the vascularity. Whether or not this is the picture that persists during the disease or whether this colloid portion of the gland is due to the administration of iodine in the pre-operative treatment, is a matter of speculation, but I believe it is highly plausible that iodine medication bears a part.

SYMPTOMS

In the past it has been the consensus of opinion that hyperthyroidism in children has a rather prolonged onset or course with the various symptoms coming on slowly, the duration of the symptoms varying from one to twelve years; in other words that acute hyperthyroidism in children is a rare observation.

This is undoubtedly true, nevertheless one of the patients in this series dated the onset of her illness to twenty days previous to her admission to the hospital, and at that time she was in a true crisis.

Carroll reports the case of a girl thirteen years of age, who was in an accident, at which time she experienced a severe fright. She developed a true exophthalmos with symptoms of exophthalmic goiter within twenty-four hours after the accident. The symptoms increased in severity and she made an uneventful recovery following a thyroidectomy, preceded, as was the usual case some years ago, by bipolar ligation. From these two cases we see that hyperthyroidism may have an acute onset.

The illness usually begins with marked nervousness and irritability, and following this the parents usually observe an hypertrophy of the gland.

Tachycardia was present in all the cases in this series, ranging from 120 to the most severe case, in which the pulse was persistently 175. The manifestation of tremor was not constant. Only one girl showed a true tremor. Weight loss was almost a constant observation, ranging from five to fifteen pounds.

Helmholtz believes that this type of case should be called true exophthalmic goiter. Nevertheless not all of these cases develop the typical ocular changes seen in this type of goiter. In fact this is a rare observation in some series reported, although Dinsmore found a large percentage of his cases with true exophthalmos.

In our series four patients showed marked

exophthalmos, one a slight degree, and three had no eye changes. All of these children showed a normal mentality; in fact the majority showed a tendency to be beyond their years mentally.

Just how accurate the basal metabolism readings are in these cases is questionable. Whether or not a way will be worked out to determine this reading more accurately remains to be seen. The rates in our series varied from plus 38 to plus 178, but I believe that these are all higher than they should be. The fact is the child with a rate of plus 35 or plus 40 may be considerably more hyperthyroid than a plus 75 or 80 when we compare the rest of the clinical picture.

TREATMENT

Treatment of these cases was that usually carried out in exophthalmic goiter, but there are two or three points that I wish to emphasize. First of all the preoperative preparation. As in the adult, Lugol's solution was our greatest single weapon of attack. However, there is a great difference in the time element necessary in the preparation of these cases. We know that the ordinary adult with exophthalmic goiter can be prepared for a thyroidectomy in from twelve to twenty days under Lugol's solution, but this is not the case in children. A great deal longer is required or the patient will not withstand any surgical procedure, no matter how slight. Two cases have been brought to my attention, the one having been prepared with Lugol's solution for twenty-one days and the other for sixteen days. In the first case a one sided lobectomy was done and in the second a ligation, but immediately after operation each patient developed a true crisis and died within twenty-four hours. From these cases I believe that instead of days for preoperative treatment, we must take weeks and often as high as three months.

As far as the operative technic is concerned, I believe it is difficult to be too radical in removal of the gland because of the tendency of the small remaining portion to rapidly hypertrophy.

Although outside the scope of this paper, I have seen two girls, fifteen and sixteen years of age respectively, who have had to undergo a second operation within a year's time for the removal of a rapid recurrence of an hypertrophic gland.

As in adults, I believe that Lugol's solution should be given post-operatively for a varying length of time, and that these patients, if possible, should be kept under observation for at least one year after operation.

SUMMARY

Because of the inconstant finding of ocular changes, I believe that this type of disease should be called hyperthyroidism rather than exophthalmic goiter, and that it is a much more common disease in young girls than previously thought. In the large majority of cases we find that some infectious disease is an important causative factor, and that shock, injury, fright, and promiscuous use of iodine as a prophylactic are very important etiological agencies. Symptoms are usually comparable to the adult type but the basal metabolism reading is not an accurate gauge of their true condition. A much longer pre-operative period is required than in the preparation of adults, and radical removal of the gland is the only possible cure.

THE INDUSTRIAL EYE*

Fred McK. Ruby, A.B., M.D.
Hibbing, Minnesota

THE rapidly increasing use of automobiles and aeroplanes together with the widespread improvements in roads, bringing high powered machinery into the outermost parts of the country, has brought the question of the Industrial Eye to every physician, no matter where located nor what line of work he may be pursuing. It is, therefore, our belief that it will be time well spent to go over, somewhat carefully, the present understanding of this most interesting subject.

In the first place there is one consideration in every eye case which is often forgotten or overlooked. That is, the vision of the injured eye at the time the patient presents himself. Often this is overlooked because of an apparent mild injury or an outlying foreign body, and later the patient returns with a report of loss of vision, when the record of a visual test at the time of accident would have saved great expense to some one for compensation or damages. It is also needless to say that money would be saved to employers, should all applicants for work be given a preliminary visual test and careful record made therefrom.

The next step is the history, if it can be obtained, of the accident or of the development of the complaint. This should be taken very carefully, as we have had foreign body cases to be charged to the Company while the man was working on his own car during working hours.

Having obtained this information, the eye should be given what we are pleased to call the external examination. Every trained eye man has spent many hours going over the external examination of eyes very methodically until at a glance he can estimate where the pathology begins and is in position to make a complete record up to this point. To illustrate: An external examination proceeds as follows:

1. The general appearance of the patient's face and the skin about the eyelids is examined for evidences of injury.

2. Lid margins are examined, openings of the various glands, then condition of the puncta followed by compression of the lacrimal sac showing presence or absence of chronic infection there.

3. The conjunctival sac is thoroughly inspected as to:

   a. That portion covering the under sides of the eyelids.
   b. That covering the globe.
   c. That in the fornix, above and below.

The cornea is next thoroughly inspected as to smoothness of its surface, clearness and evidence of previous injury as well as evidence of present injury.

The anterior chamber is inspected through the cornea and its depth noted as well as the character of the aqueous.

The iris is next noted as to its integrity as well as activity.

Finally the lens is inspected, as well as the inner contents of the eye and the fundus.

Following this the finger tension is taken before any atropine is instilled.

If there is a lack of visible injury of the eye the muscle excursions are tested.

After making this examination, the evidences of injury are now weighed and an estimate of the immediate seriousness is completed before removing a foreign body or repairing an injury. Based upon these estimations a prognosis is then made as to the possible duration of disability and as to the probable outcome.

Having accomplished this, the eye is then anesthetised, foreign body, if one is present, is removed, or removal is attempted. The eye is then given a second examination following this to recheck the amount of damage done. Under all ordinary conditions this is followed by placing the eye at rest and as a rule covering it for a period of from twenty-four to seventy-two hours, as judgment indicates.

With the patient ready to be discharged we then, again, estimate the present amount of vision, comparing it with the vision taken: (1)

*Presented before the St. Louis County Society, Duluth, August 17, 1929.

at the time of injury; (2) at the time of employment, if that has been done.

As you are well aware we have several tables estimating the loss of vision, none of which are ideal but all of which are reasonably accurate. It is our opinion that the table (see below) prepared by the Minnesota Academy of Ophthalmology and adopted by the Oliver Iron Mining Company and State Industrial Commission is of the best at the present time, although Dr. F. Park Lewis of Buffalo and other men with vast experience in this kind of work are now attemtping to provide a new table.

TABLE OF VISUAL LOSS ADOPTED IN MINNESOTA
(Minnesota Academy of Ophthalmology)

READING	PERCENTAGE OF LOSS
20/20	Normal
20/25	5
20/30	10
20/40	20
20/50	25
20/60	33
20/70	40
20/100	75
20/120	85
20/80	50
20/200	100

Before proceeding to cite cases may I say that it is our belief that all cases of industrial eyes not showing improvement from any condition in a period of twenty-four hours following first examination should be referred to a trained oculist.

What then should be the picture in first aid in an Industrial Eye?

1. A visual test if possible.

2. An external examination looking for foreign particles in the skin of the lids, conjunctival sac, cornea, etc.

3. Cleansing of conjunctival sac of foreign material, using no rough or irritating methods, nor strong antiseptics. We prefer and recommend the use of normal saline, warm, or occasionally 1-5000 cyanid of mercury used after the instillation of a local anesthetic.

4. Removal of superficially attached foreign bodies from the cornea or conjunctiva. Any foreign body involving the stroma should be removed with great care, as injury to the stroma always results in scarring of the cornea with some loss of vision.

5. Instillation of one drop of one per cent atropine in the eye except where the tension of the eye is up or where past history is suspicious of a glaucomatous increase in tension.

6. Referring of any severe or even suspicious case to a trained eye man at the earliest rather than a late date following injury. Insurance companies never dislike to pay early bills but they frequently do question late bills.

205 Power Bldg.

PSYCHOANALYSIS IN REACTIVE EPILEPSY*

FRANK WHITMORE, M.D.
Saint Paul

SINCE you are all familiar with epilepsy, you know that if we disregard the classifications which are based on the description of the epileptic attacks, all cases fall into two broad groupings: those cases in which epilepsy is symptomatic of cranial disease, and those in which no adequate brain pathology can be found and held accountable for its production. Of the latter type, which is the idiopathic or genuine epilepsy, there are certain cases in which there is present a marked disturbance of the emotions, sensibilities or feelings. There are many ways in which the emotions of this particular group of epileptics differ from those in so-called normal individuals, but the most common ones are: (1) the existence of an irritable tenseness in the interval between the attacks, which, though it may not be constantly displayed, is always very close to the surface; and (2) the likelihood that any violent emotion in the nature of anger, fright, fear or hate, may precipitate the convulsive or petit mal seizure.

The convulsive reaction of these patients to such emotional stress led Bonhoeffer to coin the term "reactive epilepsy," or to use a broader term which suggests greater involvement of the feelings or affects, Bratz uses affective epilepsy. No matter what term is used, it is merely one of description and of little consequence. The important thing is that in certain epileptics there is an abnormal emotional condition which must have its origin in the mind.

The forces which contribute to the faulty emotional state are partly within and partly beyond the scope of psychoanalysis. Within its compass are the complexes, repressions and ideals of the individual and beyond it are the personality or character of the individual and the ever present difficulty in epileptics of adjusting themselves to their family, social and economic obligations. Yet when you consider it, character and social adjustment are essentially mental reactions and are certainly influenced by our experiences. As an instance, let me say that egoism and hypersensitiveness are the dominant traits of character in the epileptic, but hypersensitiveness and egoism are interdependent because the egocentric person's interests are so narrow that they are constantly considering every contact and event in relation to themselves, and it follows that those contacts which are not advantageous to them are looked upon as slights.

This is how one patient explained the difficulty: "Even as a child I was always self-centered and self-conscious. Everything that happened seemed to travel in a circle which began and ended with my benefit in view. I struggled against the narrowness of this outlook because as I grew older I realized that my feelings were being hurt by everything that my family or friends did or said which did not definitely take my likes or dislikes into consideration."

While this view explains their sensitiveness, the egocentricity of their nature has deeper and more fundamental aspects. Some of the factors which contribute to it are, the prominence which the child assumes in the affection of its parents between the ages of one and three years; the example of egoism as a characteristic of one or both parents; certain methods of correction which make the child irritable and nervous; sexual desires and repressions in infancy, and too much praise for minor successes in early childhood. All of these factors, and many others, contribute to the child's egocentricity, and tend to bring about in the child hypersensitiveness and imaginativeness, because of the emotional involvement, and also to make it more or less tense and fearful, a typical foundation for a nervous disorder either early or later in life.

Let me report a case which developed epilepsy in her thirty-first year:

From her earliest recollection she was apprehensive, imaginative and nervous. Very early in childhood she had difficulty in sleeping; lying awake she was possessed with the fear that she would be stolen by gypsies and lost. From this fear she developed a horror of the color red, which made up the head dress and jacket of the gypsy of her imagination. Her emotions were always very near the surface, but in childhood a morbidity manifested itself and her memory now leads her to think that she spent most of her youth longing for death. She wet the bed until she was seven years old but had no other suggestion of

*Presented at the annual meeting of the Northern Minnesota Medical Association, Bemidji, Minn., Sept. 2, 1929.

epilepsy, excepting that she was shy, self-centered, emotional, and displayed a typical nervous tendency. At the age of twenty-two years her father met with financial reverses, and she had to work to help support herself and contribute to the family, and here, for the first time, it was necessary for her to make a number of adjustments in her life. She had no business education but more than the average intelligence and she entered a large office as a clerk. Within a year she was assistant to the head of the department, and as her salary increased she began to contribute to the education of a talented older sister. As she bettered her position she increased her responsibilities, so that at the age of thirty-one she was supporting herself, her mother and father, a younger brother who was in college and contributing to the support of two sisters who were studying music in New York. This burden does not suggest a selfishness of character, and yet the selfishness was present in her in a very great degree. Her personality was lively, vivacious and clever, but underneath this veneer she was cruel and ruthless. Her family held absolutely no place in her affections. She was entirely devoid of love for any of them, and still she had been supporting them for years because her mother, with uncanny accuracy, had played upon her egoism, and this by the rankest kind of flattery. The girl was wonderful, the mainstay of the family, their only support; she was worshipped, adored and palavered over incessantly. While she was entirely conscious of the fact that this was a small return for her sacrifice, still she was unable to withdraw from the situation.

This brief review of her family situation shows at least some of the difficulties which beset her, but the analysis brought to light another phase of her life.

Let me relate one of her dreams: She was walking on a hill somewhere near Seven Corners in St. Paul; on this hill the buildings flank the sidewalk and in it are many windows almost at street level. As she went down the hill she found the street blocked with a great crowd of horses which frightened her half to death. As she ran back up the hill there were many horses in each window of the building. She ran to a livery stable at the top of the hill and a man came to the door and told her she might go through the stable and out the back window, which she did. She climbed down a ladder, like a fire escape, to the street. When she finally reached the street and looked up the hill, all of the horses ran down the hill after her.

In this dream the motion, horses, horses' heads through windows and the escape and pursuit have a sexual significance. After the psychoanalysis was under way for about a month, she had related seven other dreams in which horses jumped on her, ran after her or frightened her in some other way.

This repetition in dreams is thought to have its origin in some traumatism and the following was the incident which gave rise to her horse dreams:

At the age of 23 years a man by whom she was employed part time finding that they were alone locked the office door and attempted to have his way with her. She struggled and then fainted. As she recovered consciousness, certain impressions of him made her think of him as a horse. This incident was so painful in her consciousness that she repressed it to the point where she had forgotten all about it, and, in addition, she had repressed all sexual desires by creating in her mind a hatred and contempt for all men.

This sketch then serves to add two more factors to her family and economic trials: those of traumatism and sexual repression. It is impossible to detail the effect that the necessity for adapting herself to these various situations had upon this girl, but as she bore them all she became increasingly irritable and tense. This displayed itself in a certain impatience with her work; with people who came in contact with her; in a feeling that she must get her work "done up" and by the rather stubborn tenacity with which she drove herself to accomplish her tasks. However, she carried on for about eight years, before she developed her convulsions.

To conclude this case: after explaining her situation to her and removing some of the mental difficulty and economic stress, this girl was free from convulsions for eighteen months, when she was lost from my observation.

As has already been said, epileptics are egoconscious and in the mind of each one of them there is a tangled mass of psychopathic material which promotes the difficulty they experience in adapting themselves to social and economic circumstances. According to L. Pierce Clark, a widely quoted author on the subject, the lack of social virtues, kindness, charity, love in the social sense, generosity and consideration for the feelings and rights of others, makes it difficult or impossible for them to make a social adjustment. The magnitude of their hypersensitiveness and egocentricity, combined with the degree in which the social qualities are lacking, he believes determines when, that is what time in life, they will develop their epilepsy. Those people who are very egocentric and hypersensitive and who are almost completely lacking in adaptability will develop it early in life, even if they are subject to little or no conflict with reality, while those people who have less pronounced character defects will only develop the disease when the stress of adapting themselves becomes relatively great.

While this theory of Clark's is attractive, no attempt is made to understand why epileptics should develop such a character, other than to throw the whole problem back to the unalterable factor, heredity, that is familial left-handedness, alcoholism or syphilis in the parents, hereditary burdening or such a vaguely descriptive term as the neuropathic diathesis.

In this communication no pretext is made of having solved the entire problem of epilepsy, but

the method of approach is somewhat different and it at least allows us to understand some of their reactions and ideals. Let me give an example:

An intelligent young man has had a reactive epilepsy for a number of years; it began at the age of nine. He has a vast psychopathic background, which contributes an emotional difficulty to his life. The stress in his life is briefly as follows: Since he graduated from school he has been employed by and supervised by his father, who is not only a hard taskmaster but has insisted on the young man assuming the duties of salesman, laborer, book-keeper, gardener, housekeeper and various other jobs, many of which were in competition with other healthy men. This competition, supervision, and the closeness of the family contact necessitated by his condition, has contributed to his irritability. However, to keep a certain amount of peace in the family, to hide his condition as much as possible from outsiders and to please people in business, he has assumed a certain unctuous, suave manner. The unctuousness is, of course, entirely assumed and words of endearment are plentifully scattered through his conversation, but his whole manner is so unconvincing that his efforts are clearly transparent and his effect shallow. This same man is exceedingly loquacious, bringing dates, names and circumstances into the conversation with great freedom. The purpose in this display is to convince himself, as well as his hearer, that there is nothing wrong with his mind.

Attention is called to this mechanism so frequently employed by epileptics because the literature on this subject describes the shallow feeling, the unctuous emotionalism, the superficial religiosity of the epileptic. The impression which their display of emotion makes on the observer is certainly superficial but it must be understood that their manner is purposely assumed to help them to make a social impression, and to cover up their real feelings. The very fact that they are so sensitive to the impressions which they create, and so fearful of criticism, makes them self-conscious and less able to carry off their role. If they begin to deteriorate mentally, the role they have assumed may deteriorate likewise until their utterances are disjointed phrases, religious, endearing or of superiority.

In the last case cited, reference was made to the manner in which he reassured himself of the integrity of his mental functions, and this suggests the idea that his hypersensitiveness also embraced his own body and mind as well as the impression he created in other people. In other words, was he critical of himself, and, if so, would the irritation which he felt with himself have any influence in producing the attacks? He was placed on relatively large doses of bromides so that his mental processes were decidedly slower. After the second day's administration he became very irritable. That night he had eneureses and continued to have it as long as the bromides were given. With the stopping of the bromides and the resumption of his normal mental activity, the eneuresis stopped. Whether the eneuresis was accompanied by a convulsion, or was a convulsion, cannot be told, but it may be assumed that it was one, or its equivalent.

This instance would seem to indicate that irritation arising from self-criticism was sufficient to bring on certain seizures, and further that he must have a certain ideal in regard to the manner in which his ego functioned. So, viewed from almost any angle, the emotions of the individual and their expression for the most part by irritability would appear to arise from a common source, the ego, and by ego is meant the individual's appreciation of self. If the whole fabric of epilepsy reverts back in every instance to egocentricity, then it would appear from the psychoanalyst's view, as has been asserted by Freud, that nothing can be accomplished by that method. Freud believes that the ego is a fixed point and that psychoanalysis can only be concerned with subconscious or unconscious matters which circulate about this fixed point.

This conception of Freud's is undoubtedly an artificial distinction made for teaching purposes, for a moment's consideration will convince you that egocentricity is a variable, which changes with a number of things. The invalid, for example, is more egocentric than the well person, but with the return of health the egocentricity largely disappears. This being true, the invalidism of the epileptic may determine to some extent his egocentricity, and so, even if Freud's "fixed ego concept" is true, egocentricity, or the degree of self-appreciation, is a variable quantity, and the causes for it lie within the scope of psychoanalysis. Psychoanalysis will remove some of the psychopathic mechanisms present and increase our understanding of their personality and their moods.

THE PHYSIOLOGY OF SPINAL ANESTHESIA*

RUSSELL J. MOE, M.D.
Duluth, Minnesota

WITH the recent popularization of spinal anesthesia many attempts have been made to explain the various phenomena which take place. It was with the idea of correlating the explanations of these phenomena that this paper was written.

In spinal anesthesia or subarachnoid block, a block is produced which prevents impulses being conducted through the anterior roots to the spinal nerves, or in the reverse direction from the spinal nerves through the posterior roots to the spinal cord. The anesthetizing drug, novocain for example, sets up a chemical reaction with the nerve tissue producing a physiological block. This block occurs at the anterior and posterior roots of the spinal nerves within the dural sac, because here they are more sensitive to and more easily permeated by the drug.

Not all of the fibres in the nerve roots are similarly affected. Some fibres are more resistant than others. Evans[2] states that the fibres are blocked in the following order:

1. The fibres which carry pain and temperature sensations from the skin and viscera.
2. Those fibres which arise from the skin and convey the sensation of touch.
3. The fibres which carry impulses of pressure or movement from muscles.
4. The fibres which carry impulses to the skeletal muscles.
5. The sympathetic nerve fibres which receive stimuli from the viscera and send out, among others, impulses which regulate the vasomotor system.

Thus, one can see that those fibres having to do with the sensation of pain are most affected, while those having to do with vasomotor control are least and most fleetingly affected. Therefore, in spinal anesthesia, there is first loss of the sense of pain, then of tactile sense, then motor sense, then of muscle power, and finally of vasomotor control. As the depressant or blocking action of the drug wears off, conduction through the nerve fibres gradually returns to normal and the lost functions return in the reverse order.

The anterior nerve root carries the motor fibres, while the posterior nerve root carries the sensory fibres. The posterior or sensory root is more readily affected by the drug, thereby producing loss of pain, temperature and muscle sense, while the anterior root is affected to a lesser degree. Besides this, there are several factors which favor a more concentrated solution upon the posterior roots. The first of these is the point of injection. The anesthetizing drug is injected posteriorly and therefore must necessarily come in contact with the posterior roots first, and will be more dilute when it reaches the anterior roots. Secondly, the interarachnoid trabeculæ, between the arachnoid and pia mater, hinder to some degree the diffusion of the drug anteriorly. Lastly, the position of the patient, which is on the back, and the specific gravity of the injected solution, tend to keep the more concentrated solution about the posterior roots.

There are certain phenomena which accompany spinal anesthesia that are of considerable interest. One of the more important of these is the fall in blood pressure. There are three factors concerned here. The first of these is the loss of vasomotor control. Normally there is a balance set up between the vasoconstrictors on the one hand and the vasodilators on the other. This balance is regulated by the vasomotor center. Now, if the vasoconstrictors, which tend to keep up the blood pressure, are paralyzed, then the vasodilators are overactive, the blood vessels dilate, and the blood pressure goes down.

Experiments on animals have shown that, as the spinal cord is cut, various drops in blood pressure occur, depending upon the level at which the cord is severed. For instance, cutting the cord at the level of the first thoracic

*From the Duluth Clinic, Duluth, Minn. Read before the Minnesota Surgical Society, Duluth, Minn., Sept. 14, 1929.

segment produces a maximum lowering of blood pressure. A mid-thoracic section would produce a less marked drop, while a section through the lumbar region would result in very little or no drop. The same mechanism is involved when spinal anesthesia is administered, and the degree of drop is determined to a large degree by the height of the anesthesia. In practice, this drop in blood pressure is overcome in some degree by the administration of ephedrin[6] or adrenalin, which act peripherally to stimulate the vasoconstrictors, and thereby maintain or elevate the blood pressure. Many cases* maintain the blood pressure at the normal level; others will show either a fall or a rise of ten to twenty millimeters, and only occasionally is the drop sufficient to cause any alarming symptoms.

The second factor involved in the blood pressure drop is the paralysis of the thoracic and abdominal muscles. By this paralysis the pumping or aspirating action of the thorax is lost or diminished and a smaller volume of blood gets to the heart. In other words, the minute volume is decreased.

The third factor is the slowing of the heart rate. Here again there are two nerve supplies which are antagonistic in their action—the vagus or inhibitory nerve, and the sympathetic or accelerator nerves. The vagus arises from the medulla and soon becomes extradural. The sympathetic nerves arise from the first to the fourth thoracic segments, and pass out as part of the anterior nerve roots. Thus, if the anesthetizing drug reaches these nerve roots there will be a block, and the amount of block will determine the amount of slowing of the heart rate. The vagus will become overactive and the heart rate will be decreased.

Another interesting phenomenon which is met with is that which, for want of a better term, is called "increased peristalsis" or "contracted gut." The same mechanism which explains the drop in blood pressure and the slowing of the heart rate will explain to some degree this last phenomenon of contraction of the intestine. In this case the sympathetic and the parasympathetic systems are again antagonistic. The sympathetic fibres arise from the lower thoracic and upper lumbar segments, while the parasympathetic impulses are carried through the vagi and the pelvic nerves. The vagus supplies the small intestine, the ascending and transverse colon, while the pelvic nerve supplies the remainder, *i.e.*, the descending colon, sigmoid, rectum and anus. The sympathetic fibres exercise an inhibitory action on the intestines and the parasympathetics a contraction. The fibres which make up the pelvic nerve are always paralyzed in a spinal anesthesia, as it arises from the sacral roots, so one can see why we have a contracted gut and a relaxed anal sphincter. There is a partial or complete blockage of the sympathetics, allowing the vagus and the intrinsic nerve supply to become overactive, resulting in increased peristalsis. Whether or not the antagonism between the sympathetic and parasympathetic nerves is as definite as it would seem here is doubtful. However, Alvarez[1] states that the first effect of stimulation of the vagus is generally a slight lowering of the tone of the stomach and bowel, and this is followed in a few seconds by an increase in tone and activity which may last for from a few seconds to a minute. He goes on to state that Spodolini and others have shown that one can get purely inhibitory effects by stimulating the vagus, just as one can get purely augmentatory effects by stimulating the splanchnics. Ordinarily the main effect of stimulating the splanchnics is an inhibitory one. Certainly, at least, the antagonism does not seem to be as definite as in the vasomotor system.

Lapicque[4] introduces a vital and novel theory to explain not only inhibition and anesthesia but fundamental selectivity in nerve reactions. According to his theory one neurone system can stimulate another only if the "temporal characteristics" of both are equal or nearly so. This "temporal characteristic" harks back to a hookup of nerve connections based not so much on direct continuity as in a set of electric bells or a telephone system, but rather as a "tuning in" arrangement such as obtains in radio. On such a basis any local or general anesthetic need not so much mechanically deaden pathways of sensation as to close them by changing their "vibration," "wave length," or "tuning in" properties.

If one eliminates the reflex nausea and vomiting brought on by manipulation of viscera

*Personal observations based on 600 inductions of spinal anesthesia for operations below the diaphragm.

in the upper abdomen, especially the stomach and duodenum, there remain two other factors which produce nausea and vomiting. The first of these is cerebral anemia, which is produced by lowering of blood pressure and slowing of the heart beat, and is relieved when these two phenomena return to normal. The second factor is that of psychic influence, and can be traced to poor appreciation of psychic factors on the part of the surgeon, anesthetist, or anyone who comes in contact with the patient during or just preceding the operation.

The cause of death in spinal anesthesia has received a good deal of attention, and the best evidence points to cerebral anemia rather than respiratory paralysis. Koster and Kosman[3] state that with a marked dilatation of blood vessels within the abdomen and the consequent tremendous fall in blood pressure, the venous return flow to the heart becomes so inadequate that not enough blood can be pumped out to the brain. Failure to supply blood to the brain in sufficient quantity results in a bulbar and cerebral anemia which is responsible for death in spinal anesthesia. When respiratory paralysis ensues, it is consequent to the cerebral anemia. Koster and Kosman[3] have done some very good experimental work to confirm this.

In conclusion, just a word about the duration of anesthesia. The factors which affect the length of anesthesia are the dosage and concentration of the injected drug. The average duration for upper abdominal operations is about one hour, for lower abdominal one and one-fourth to one and one-half hours, while for operations on the perineum and lower extremities many spinal anesthesias will last for one and three-fourths to two hours. There is also a personal variation. Patients having the same operation, and being approximately of the same size, all other things being equal, will often show a variation in duration of anesthesia. However, for all practical purposes the duration is sufficient to perform most major surgical procedures below the diaphragm.

TREATMENT BY ROENTGEN RAYS IN OVARIAN DYSFUNCTION*

Frances A. Ford, M.D.
Rochester, Minnesota

WITH the rapid extension of radiotherapy to the numerous uses for which it is now recommended, a roentgenologist must be keenly aware of the danger of over-enthusiasm for any particular application because of the danger of later discredit to the entire field of treatment. However, it is equally important, not only for the roentgenologist, but for the surgeon and internist, to keep sufficiently in touch with rapidly developing clinical experience and the accumulating knowledge of the biologic reactions caused by the rays in graded doses on normal and abnormal tissue to give their patients the benefit of such treatment in conditions particularly amenable to it. The profession as a whole, as well as the radiotherapist, should know the relative susceptibility to the rays of the normal tissues of the body and of the different types of malignant growths, and it should know something of the potentialities of treatment by radiation in both acute and chronic inflammatory processes.

A newer field, and one which is in need of critical study, is the use of radiotherapy in certain endocrine dystrophies, particularly because in this field clinical criteria for the diagnosis of disease entities are inexact, and knowledge of the interrelationship of various glands is limited. For the last three years, Dr. Drips and I have been interested in the use of radiotherapy in low dosage in certain cases which may be regarded as representative of the state of ovarian hypofunction or dysfunction. In two previous publications we have considered more fully the basis of diagnosis of this condition and the development of both ovarian and hypophyseal irradiation in its treatment. With only brief recapitulation of the salient features of this syndrome and the technic of the treatment, I wish to present at this time reports of six cases to illustrate some of the possibilities of radiotherapy in low dosage in this field.

Ovarian dysfunction can be rather loosely defined by stating that in a certain group of patients abnormalities of menstruation and of reproduction (sterility or frequent abortion) can, by exclusion of any organic local or general disease or structural abnormality, be attributed only to incompetence of the ovaries themselves. The most common manifestation of this ovarian disturbance is lack of rhythm or cycle in menstruation, exhibiting either suppression of menses (oligomenorrhea or long periods of amenorrhea) or the reverse (too profuse, prolonged, or too frequent flowing). All combinations or interchange of the two phases of alteration are found. Intense dysmenorrhea, distinct from the obstructive type, frequently accompanies these disorders and sterility is likewise an almost invariable corollary.

On general examination, often confirmed by exploratory operation, little change from the normal pelvic conditions can be determined, or at least the variation in size, position, or condition of the uterus and ovaries is within the range of variation found compatible with normal menstruation in many persons.

To limit the group for more accurate study, Dr. Drips and I have endeavored to exclude cases of obvious pluriglandular dystrophy, although in some of these, undoubtedly, the same treatment may have an alleviating effect, and its use may be indicated. That the dysfunction represented is essentially an ovarian hypofunction is evidenced by the palliation afforded in many instances by the use of ovarian extracts and also by the similar symptoms which occasionally arise after pelvic inflammatory disease or after operations in which resection of the ovaries has been performed. Many of the more severe cases have proved intractable to the commercial preparations of ovarian substance now available and

*From the Section on Roentgen-Ray Therapy, The Mayo Clinic, Rochester, Minn. Read before the Association of Resident and Ex-resident Physicians of The Mayo Clinic and The Mayo Foundation, Rochester, Minnesota, October 8 to 10, 1929.

it is in these more resistant cases that treatment by roentgen rays is employed. Two methods of treatment have become fairly well standardized and are in use in many European and in some American clinics; namely, the application, to either the ovaries or to the hypophysis, of a very small amount of roentgen rays. The range of dosage is approximately 5 to 10 per cent of an erythema dose at the depth of the organ treated; rays of short wave length are used. Although we have had occasion to employ both forms of treatment, we have found the ovarian irradiation or a combination of both ovarian and hypophyseal irradiation more effective, as a rule, than the pituitary irradiation alone. Approximately two decades of observation of patients treated by this method, together with many experimental studies and some data based on histologic studies of ovaries from women following irradiation with this dosage, had not shown indication of harmful sequelæ to the patient or to the subsequent offspring. This latter point had been the alarm of the general profession or at least those unacquainted with the significance of dosage of rays in proportion to biologic reaction which can result. Few clinicians hesitate to subject a patient to roentgenographic examination and often repeated examinations of the colon, of the spine and pelvic bones, or of the urinary tract, on any suspicion of disease in these structures, but many of these same clinicians are strongly prejudiced against the use of an almost analogous amount of irradiation in treatment. The recent extensive survey by Murphy of the incidence of congenital or constitutional defects in children born to mothers who had previously been subjected to pelvic irradiation, often in considerable amounts, such as is used in the production of temporary sterility or in the treatment of fibromyomas, should answer conclusively these doubts.

Case 1.—A woman, aged twenty-two years, 5 feet 5.5 inches in height, weighed 170 pounds. Menstruation had begun at the age of thirteen years. It always had been irregular and scanty and had ceased suddenly six years before admission to the clinic. Since then she had menstruated only once and that two years before admission. She had had no vasomotor symptoms and no molimen.

The uterus was small, in the anterior position, movable, and the ovaries were palpable.

Previous treatment had included ovarian extract, 10 grains three times daily, for six months, and intravenous organotherapy, probably with corpus luteum. This treatment had been without results, and no medication had been given for one and a half years.

Irradiation of ovaries was given in June, 1928, and a reduction diet was advised. Supplementary treatment with organ compounds was not given. After irradiation the patient experienced some pain, low in the pelvis, for about a half hour every few days. Six weeks after treatment a dark, hemorrhagic vaginal discharge occurred which continued for five days. The patient returned in August, 1928, encouraged by this indication of return of ovarian function and anxious to continue treatment. Combined pituitary and ovarian irradiation was given. Since then menstruation had occurred every six weeks to the date of the last observation, August 5, 1929. Menstrual flow is normal for one and a half days, and then there is a brownish discharge for three days. The patient experiences slight pelvic discomfort with the periods; her general health is excellent.

Case 2.—A single woman, aged twenty-four years, 5 feet 4.5 inches in height, weighed 240 pounds. Menstruation had begun at the age of eighteen years. It always had been irregular, scanty, and associated with severe pain. There had been excessive gain in weight since puberty. She had frequent headaches.

The uterus was small and lesions were not found in the adnexa. The basal metabolic rate was +12. Obesity was graded 4. There were no acromegalic features.

Previous treatment had included appendectomy and bilateral salpingectomy for early tuberculous salpingitis, and puncture of small cysts in the ovaries, four years before admission to the clinic. Menstruation and general health had not improved following operation.

Irradiation of the ovaries was given in June, 1927, and a reduction diet was advised. Supplementary treatment with organ compounds was not given. Menstruation occurred regularly every month from June, 1927, to May, 1928, at which time septicemia with high fever occurred. Since then there has been no menstruation. During the time of regular menstruation the patient improved greatly in general health and her weight was reduced to 214 pounds.

Case 3.—A married woman, aged thirty-two years, 5 feet, 1.5 inches in height, weighed 213 pounds. Menstruation had been fairly regular until the patient was twenty-two years of age. Since then it had been infrequent and scanty, with intervals from two months to two years, and a rapid gain in weight. Hot flashes were frequent, and molimen was present. The patient desired children. Pseudocyesis occurred twice.

The fundus of the uterus was normal and movable, and lesions were not found in the adnexa. The basal metabolic rate was +15. Roentgenogram of the sella turcica did not show abnormality.

Previous treatment had included ovarian extract over long periods, which occasionally had caused a slight hemorrhagic discharge or increase of molimen.

Irradiation of one ovary was given in January, 1927,

a reduction diet advised, and agomencin (an ovarian preparation) prescribed to be taken for one week before the expected menstruation. Menstrual flow occurred two days after the irradiation and continued for one month, following which normal menstruation occurred from April to August, 1927. Each period lasted about one week. In August the patient became pregnant, and in May, 1928, gave birth to a female child; the child was well developed and apparently vigorous, but died two hours after birth from respiratory failure. The attending physician reported that the birth had been slow and difficult due to the extreme obesity of the mother, and he could account for the death of the child in no other way. Menstruation was reëstablished on one occasion following the birth of the first child before the second pregnancy occurred. A male child weighing 8.5 pounds was born in May, 1929. The child is now five months of age, weighs 16 pounds, and is healthy and well developed in all respects. The mother reports her health better than at any previous time; she mentions particularly that the soreness of the flesh of the entire body, which had been so noticeable during the periods of amenorrhea, is now relieved. Two menstrual periods have occurred since the last childbirth.

This has been the only case in our series in which pregnancy has followed reëstablishment of menstruation. Kaplan has published a series of thirty-eight cases treated for amenorrhea in which menstruation was reëstablished in thirty-two. In thirty of the group who were married and previously sterile, pregnancy occurred in eleven instances, two miscarried, and nine healthy children had been born. Linzenmeier also has reported his experiences, with similar results. Congenital defect attributable to irradiation was not present in any of the children.

Case 4.—A single woman, aged twenty-four years, had begun to menstruate at the age of twelve years. Menstruation always had been irregular, and the average interval between periods was six weeks. Intense dysmenorrhea had occurred for the last nine years. The most severe pain occurred on the first day and always required morphine for relief. The patient occasionally lost consciousness from pain before the hypodermic was given.

There was no pelvic abnormality.

Previous treatment included dilatation and curettage in August, 1925, without relief. Large doses of ovarian extract were taken two weeks before each period, but had given no result after several months' trial. A second dilatation and curettage and insertion of Baldwin tube, which remained in position for six weeks, was likewise without effect.

Irradiation of the pituitary gland was given in June, 1928. There was slight improvement of the period which immediately followed the irradiation. The treatment was repeated in July. The next two periods were much less painful. Because complete relief had not been obtained, an ovarian irradiation was added in September, 1928. Since then the patient has been either free from pain or experiences slight discomfort for a few hours at the beginning of menstruation. This discomfort is amenable to ordinary remedies such as aspirin.

Case 5.—A single woman, aged twenty-four years, had had severe dysmenorrhea for five years following appendectomy. The pain incapacitated the patient for work. Menstruation was irregular, with intervals of five to seven weeks, and there was pain and nausea one week to sixteen days before menstruation began. The patient was confined to bed with each period, vomiting every fifteen to thirty minutes during the first day. There was severe backache and abdominal cramps.

The fundus of the uterus was small and retroverted, and lesions were not found in the adnexa.

Previous treatment included ovarian extract, 10 grains three times daily for two weeks before the menstrual period, corpus luteum, and Hammond's mixture, without effect. Benzol stearate was given to relieve spasmodic pain at the time of the menstrual flow, but could not be retained because of vomiting.

Irradiation of the hypophysis was given in June, 1928. The July period was much better. There was a return of nausea with the next period, although the pain was less severe. A second pituitary irradiation was given in October, 1927. The patient was entirely free from nausea and pain until January, 1928. There was slight dysmenorrhea then, and apprehension of further trouble led to the third treatment. Since this time the patient has been well. She has completed two years of nurse's training since the second treatment, and has not lost any time from duty because of illness.

Case 6.—A single woman, aged thirty years, came to the clinic complaining of menstruation which, although regular, was profuse, and accompanied by intense pain for thirty-six to forty-eight hours. There was a marked state of chronic nervous exhaustion, due chiefly to dysmenorrhea.

The uterus was retroverted and the ovaries distinctly palpable.

Previous treatment included internal shortening of the round ligaments and dilatation and curettage in March, 1929. The ovaries were described by the surgeon as elongated (5 to 6 cm.) with heavy capsules, the surface of which presented rugæ. The cervical canal was not of the rigid type seen in obstructive dysmenorrhea. The menstrual periods in April and May were associated with the same intense pain.

Irradiation of ovaries and of the pituitary gland was given in May, 1929. There was marked relief from dysmenorrhea for the next two periods. A slight return of pain, relatively mild and of short duration, occurred with the third menstruation. The patient gained weight and strength. The amount of menstrual

flow was distinctly lessened. An examination in September, 1929, showed the ovaries still large and tender, and the uterus small and anterior in position. A second ovarian irradiation was given in September, 1929.

Treatment has not been equally successful in all cases; there have been some complete failures, but the results in over 50 per cent of the cases treated have demonstrated conclusively the potential effectiveness of the method. Improvement in results may be expected with more careful study of the types of dysfunction within the group as a whole, and perhaps through combinations of various irradiations of endocrine glands such as those recently advocated by Borak. With the development of more effective extracts of organs, radiotherapy probably will be superseded by direct substitution therapy, but in the meantime it would seem to have a definite field of usefulness.

CASE REPORT

THE TETANOID SYNDROME IN PREGNANCY

REPORT OF CASE

EVERETT C. HARTLEY, M.D.
Saint Paul

In a recent article[1] it was suggested that a group of symptoms, rather commonly observed in pregnant women, probably due to a relative hypocalcemia, be considered as a tetanoid manifestation and that the group of symptoms be classed as the tetanoid syndrome. These symptoms are achy or crampy pains in the legs and thighs, an irritability of disposition unusual to the patient, insomnia, an edema apparently not associated with cardiac or nephritic pathology, and paresthesias of the extremities.

The symptoms comprising the tetanoid syndrome complicating pregnancy are nicely illustrated in the following case report. The patient is one of the series being studied at the Wilder Obstetrical Dispensary through the kindness of Dr. J. L. Rothrock, and I am indebted to the same source for the opportunity to interview the patient after delivery at the Miller Hospital and to study her hospital record.

Mrs. P. F., white, aged 36, gravida X, had one miscarriage at three months between her seventh and eighth pregnancies. Six children are living; three are dead—one due to convulsions at about three months of age, one to meningitis at three months, and one due to a six weeks premature delivery.

The patient herself had scarlet fever at fifteen years and was seriously ill at a hospital for six weeks. Chorea followed this illness and lasted for about four months. At sixteen she had an appendectomy. She has been under observation for tuberculous pleurisy which probably healed. She has also been treated for some tuberculous affection of the eyes. In spite of her illnesses and numerous pregnancies the patient appears strong, healthy and vigorous. Laboratory reports Kolmer Wassermann 4 plus, and Kahn 3 plus.

Her early pregnancies were uneventful. The seventh and eighth, however, presented symptoms identical with the ones here reported, except for the fact that they appeared during the eighth month while with this they appeared, in part, as early as the fourth month.

In this pregnancy edema of the feet and ankles appeared in the fourth month. Towards the latter part of her pregnancy she also had edema of the hands, while that in the lower extremities had become pronounced, pitting deeply on pressure. Varicosities became conspicuous in the later months; considerable areas about the legs and ankles were colored a deep bluish purple over the veins with the adjacent areas a washed-out indigo.

About four weeks before term insomnia became an annoying symptom; the onset of crampy pains in the legs and feet at the same time probably accounts for the insomnia in some degree. She became increasingly nervous and irritable and cried easily. When seen ten days before delivery at the dispensary she impressed one as being mildly hysterical, speaking of her various symptoms with tearful, anxious hopelessness. The urine was free from albumin throughout the pregnancy; B. P. 110/60. Her hands and feet often felt numb. She would pound her hands on her knees in an effort to get some feeling into them.

During the last month she made only one visit to the dispensary because walking was so difficult on account of pain in her feet.

On July 19 she was given 40 units of parathormone intramuscularly. At the same time she began taking calcilact, 1 teaspoonful four times daily. On July 20 the edema had almost disappeared. The paresthesias and crampy pains in the extremities completely disappeared. By the twenty-first the edema was entirely gone, together with most of the discoloration. She slept soundly. On the twenty-second she took a long walk, the first in many weeks. She went into labor on the twenty-second, and spontaneously delivered a baby weighing 8 pounds and 2 ounces after a labor lasting only four hours. This is remarkable in comparison with the two labors preceding, which both lasted five days, with babies weighing respectively 5 pounds 2 ounces and 6 pounds 8 ounces. The puerperium was afebrile throughout. She slept soundly, and was entirely free of nervous manifestations, edema, parasthesias, and cramps.

Discussion.—When one considers the demands made upon the calcium metabolism of the mother by the growing fetus, and by lactation, it is not surprising to find that occasionally the apparatus fails to fully satisfy the demands made upon it. It is an old observation that tetany develops more readily in either humans or animals during pregnancy and lactation, or even during menstruation, than at other times. "Rheumatic contracture of nursing women" was proposed by Trousseau in 1854 as a name for the condition. McCarrison[2] has observed the very marked tendency for the women of Gilgit Valley in India to develop tetany during pregnancy and lactation. Williams[3] gives Dibbelt's estimate of at least 0.17 grams of calcium oxide daily as the average demand for calcium during the second half of pregnancy. Bar (from Williams) calculates that in the last two months this must be increased to 0.638 grams daily.

It is difficult to observe edema in pregnancy without a sense of alarm. Our teaching has been to accept it as a manifestation of toxemia, and toxemia, in turn,

means grave warnings, anxiety, and complete disruption of any ordinary manner of living. Even when the diagnosis of toxemia is made questionable by the absence of the usual accompanying signs, it has been the conservative practice to treat such patients as potential toxemias. When nephritic pathology is absent, however, as in this case, and where other tetanoid symptoms exist, one may conclude that toxemia probably does not exist, nor even threatens; certainly the patient need not be subjected to the discomforts, anxiety—perhaps dangers—which attend anti-toxemia measures. The nature of the edema in this condition is uncertain. In the article referred to, Faltas' conception of it as an angiospasm is given, but this does not seem to be so likely as the idea that it is the result of an alteration in blood-vessel permeability due to the low calcium content of the blood.

Insomnia in these patients is often extremely annoying, not only to the patient herself, but to her physician as well, since she responds so poorly to the usual soporifics. The cause of this symptom is probably related to the other nervous manifestations, including the cramps and paresthesias, and as such would be an expression of the heightened irritability of the nervous system. The bearing of this condition upon the duration of labor has been elaborated somewhat in the reference and is one of its most important aspects. There is a relative inertia of the uterus and a tendency to post-delivery atony. It is in this type of uterus that the muscles may have the power to dilate the cervix, but fail in that expulsive force so imperative to the normal progress of the second stage. Such patients may labor for hours and days, suffering from the pains of labor and despairing because of their futility. The problem is usually solved by some type of operative delivery with a danger all the greater because of the exhaustion of the patient, the probable high level of the fetal head, and the (usually) frequent examinations made to ascertain the cause of the delay. It is remarkable that pituitrin has but little effect upon the uterine contractions in these patients; even extraordinary amounts may be given without perceptibly altering the rate or the force of contractions.

How often this condition may produce a prolongation of labor is not known. An effort is being made at the present time to determine the incidence of the condition in a considerable number of obstetrical patients being observed over a period of one year. Difficult labor due to a discrepancy between the size of the child and that of the birth canal or to unusual positions of the child must of course be ruled out. The chief indication of the condition must be the clinical history—and the condition should be relieved before its possible effect upon the progress of labor becomes apparent.

Treatment.—Measures tending to stimulate calcium metabolism are used, and calcium itself is given in some palatable form. Calcilact has been found an agreeable form to most patients, and four or five teaspoons of this may be given daily. Calcium chloride may be used intravenously, especially in the more severe forms. For stimulating calcium metabolism the parathyroid gland extract used intramuscularly is apparently the most effective agent. Viosterol may be used and seems adequate where the symptoms are comparatively mild.

President's Letter

THE practicing physician has heretofore looked upon preventive medicine as a state function, to be performed by official boards of health. He has conceived of this function as applying to groups of people and in relation to the discovery and eradication of the causes of such diseases as tend to be endemic, epidemic and pandemic. He appears rarely to have sensed the idea that applied preventive medicine is also an individual matter and is just as surely a part of his business as is the treatment of measles, mumps, whooping cough or diphtheria.

It is certain that this attitude is very largely, if not wholly, responsible for school boards, health boards and lay health associations taking up such work as wholesale vaccinations against certain of the contagions.

The State Board of Health has ever stood ready to aid in making various biologic products for the prevention and cure of disease easily and cheaply available to public and physicians alike. The physician has been quick to avail himself of any such preparations when needed to aid in effecting the CURE of disease, but there he is apt to stop. He has been so ingrained in the habit of trying to cure disease after it has developed that he has been almost stone blind to the necessity of treating the unexposed healthy person for purposes of prevention.

The physician must become health-minded. He must learn to look upon himself as a health physician, *i.e.*, one who is ever on the alert for the recognition of the earliest and hidden signs of disease; one who is ever on the alert to avail himself and his people of the accepted methods for prevention of illness.

The campaign for wiping out diphtheria will be in full swing before long and it will become the duty of each and every one of us to aid earnestly in putting into effect plans for the general use of toxin anti-toxin.

It has been said that if every man, woman and child could be given preventive doses of toxin anti-toxin, diphtheria would be completely eradicated. What a boon that would be! What a boon to childhood! For it is in the tender years that this disease is most contagious, most easily overlooked and therefore most fatal.

The method by which this preventive treatment may be given to large numbers of children will vary in different localities. Whether it shall be done by local doctors, by the health department or by other agency is for the local profession to decide. It would seem that the logical way would be for the local profession to treat those who are not indigent; the rest should be taken care of at public expense.

Before any of this work can be done, however, the public must be apprised of the dangers of diphtheria, preventive value of toxin anti-toxin and its harmlessness.

It is our duty to live up to our ancient traditions. The public looks to us these days to PREVENT disease. They are calling to us. We cannot fail them! The physicians in every locality in the state should take the *initiative* in this work. They can commandeer all the organized health agencies to their service. They can, if they so desire, have the help of the extension service of their Committee of Hospitals and Medical Education, their Committee on Public Health Education, and of any individuals or groups they might consider helpful. They have but to ask to receive.

PHYSICIANS! START THIS CAMPAIGN OF EDUCATION AND CARRY IT TO ITS LOGICAL AND BENEFICENT CONCLUSIONS!

Vol. XIII March, 1930 No. 3

MORE NARCOTIC LEGISLATION

No one is more anxious to prevent narcotic addiction than the physician, and the profession as a whole is only too willing to coöperate with the government regulations necessary to limit the use of habit-forming drugs to proper channels.

Various estimates have placed the number of narcotic addicts in the country at figures ranging from 15,000 to five million. The very nature of drug addiction makes accurate determination of the number of addicts impossible. Even though the low estimate is right every effort should be made to cut it down.

As a result of a seeming increase in the number of addicts in the country the Harrison Act was passed in 1914. Various amendments have been added from time to time and the Porter bills now before Congress have attracted attention to narcotic legislation.

The Harrison Act was supposed to direct the use of narcotics to legitimate channels. What it really was in the main to direct their use *in* legitimate channels. This was so evident that the public gained the impression that the law was directed against the medical profession. By inference at least the medical profession was blamed for a large part of the abuse of a most valuable drug. The fact remains that financial gain on the part of those selling narcotics illegally to addicts is the main cause for the spread of addiction. The percentage of addicts made so by careless physicians must be very small. The few unprincipled physicians who profit by aiding addiction cannot be too severely condemned and should be punished to the full extent of the law. Enforcement of law should be specially directed against such unprincipled offenders.

Certain provisions of the Harrison law have been needlessly strict and irritating to both physicians and pharmacists—so much so that certain pharmacists have refused to handle narcotics at all and certain physicians have refused to treat addicts for fear of penalties attached to infringement of over-rigid and ambiguous regulations. The physician must keep a record of narcotics administered in the office; must use special requisition blanks for morphine tablets; cannot order a prescription containing codein above a certain amount by telephone; must observe certain incomplete regulations in treating an addict in an institution, and so on.

Registration by physicians licensed to administer narcotics is required each year and an oversight does not relieve the physician of the pen-

alty, hich may be $2,000 or imprisonment for five years or both. As a matter of fact, anyone who violates or fails to comply with any provision of the Harrison law is liable to the same penalty.

As though the present law were not stringent enough in regulating physicians, now come the Porter bills mentioned in the editorial of the A. M. A. Journal of February 8, 1930. One of these bills has already been presented to the House and if enacted no physician who has been convicted of any offense against the present narcotic law, no matter how trivial, may ever be licensed to administer a narcotic again. All regulations are to be made by the Commissioner of Prohibition subject to approval of the Secretary of the Treasury. The physician whose rejection of application for a license is impending must show cause why a license should be issued or why his license should not be revoked—in other words is considered guilty until he proves his innocence. The defendant has no voice in determining the place of hearing, whether it be public or private, and no rights as to who shall be subpœnaed as witness. Only the Commissioner of Prohibition may pass on the evidence submitted. Provision is made for appeal to the courts from decisions rendered by the Commissioner.

The second Porter bill provides for the creation of a special Commissioner of Narcotics. As stated in the editorial this centralized bureau in Washington will have dictatorial right in determining what physicians licensed by the respective states shall be allowed to administer narcotics. We physicians will have a Mussolini in Washington to dictate whether or not we may prescribe narcotics. Such high-handed legislation merely sets the scene for trouble, and violations of a needlessly strict law will result.

The present and proposed narcotic legislation is missing the point. Instead of giving dictatorial power to a Bureau in Washington to regulate physicians, it would be far better to concentrate the energy of the Bureau on the illegal peddling of narcotics outside of the profession.

The regulations proposed in these Porter bills border on tyranny, and every physician in the state should do his part in defeating these bills. Write your representative in Washington.

APROPOS OF MEDICAL COSTS

Mark Hanna has been credited with the remark, "Money and machinery entered the world at the same time." He was interested in accumulating and using both—and time is according him much credit. Diagnosticians of social and political ills have not failed of late to feature the load placed on society by the recent triumphal expansion of medical service. Could this have been an isolated expansion while the mass of the people retained their former alignments we would not have so much of the criticism appearing in papers and magazines. A machine age, however, with revolutionary changes in money distribution; high wages, and long periods of unemployment; installment buying and poor family budgeting—these and many more trends have brought not only expensive but chaotic living.

One searches a long article in the American Medical Association Bulletin* for some tangible expression other than excellent historical references and philosophical applications; some intimate criticism of doctors that minimizes their human frailties and points to their group salvation. Doctors are just as much out of social adjustment as other restless groups. We also have been touched by those agencies mentioned by the famous Ohio senator. Who, among us, have bought more cars than doctors, or more radios or cities' "serpents"! The generation before us bought fast horses and profitless farms. We need some of that epicurean advice which "calls not so much for an increase in our estates as a decrease in our desires." A reader chuckles and quotes the Chinese proverb for the benefit of this writer: "The mandarin from his chair sings of the many blessings of poverty!" No medical doctor of today, blessed with even a fair personality, need fear impoverishment. If it is his lot, it may be from accident, but can usually be traced to an overgreediness for fees, an overestimate of his own powers and prerogatives, or an asinine eagerness in investment which sends him "out wool gathering," but returns him "well shorn." Therefore, a lot of this preachment about chang-

*Hall, Harry M., A. M. A. Bulletin, Vol. 24, No. 9, p. 230; "DesCartes Was Right."

The article begins with the quotation, "If ever the human race is raised to its highest practicable level intellectually, morally and physically, the science of medicine will perform that service."—*Rene DesCartes.*

ing the attitude of the public toward us is plain bunk.

Let us adjust ourselves, our attitudes, our fees and hospital costs, to meet fair human needs. Before we launch tumultuous propaganda in order to adjust our patients to our ideas, let us practise a few adjustments among ourselves. It is difficult indeed to keep up with the strides in our own profession; it is necessary to attend many medical meetings and to organize our work at home. No better means of keeping the public with us has ever been devised than to let them know by our work that we are alert and ever seeking the light. Just as we must deal with individuals who need our attention, the public in turn must deal with us largely as individuals.

Medical service must remain a piece of handiwork that machine methods and mass production cannot well do. Louis XIV paid two hundred thousand dollars to the man who dared lance his royal rectum. At the same time, most of his subjects defended their health with charms, grog and prayer. Grog is still considered notably effective by a large percentage of our population. There are obviously gross inequalities in the capacity or ability of people to meet the cost of accident and disease. The one notable equality is that of desire, whether it be in terms of luxuries or necessities. Hence it is that many good folks assume needless burdens of medical and hospital expense, and doctors for the most part find it most difficult to keep them from doing so. For a considerable portion of our economically soundly organized countries a king with empyema gets about the same treatment as does his meanest servant. Indeed, we may answer DesCartes: "Some parts of the world have been remade by doctors."

E. L. T.

CASCARA-AGAR NOT ACCEPTABLE FOR N. N. R.

The Council on Pharmacy and Chemistry reports that, under the name "Cascara-Agar," the Reinschild Chemical Co. markets a preparation stated to contain "15 per cent of a watery percolation of two-year-old cascara bark, which is processed into No. 1 Agar, cut to size" and is recommended for use in constipation. It is stated on the trade package that the preparation is: "A harmless vegetable addition to breakfast food. Each teaspoonful contains a mild and specially prepared solution of Cascara Tea." Since no statement as to the amount of cascara contained in the product was given, the firm was asked to make a plain statement of the constituents of the product. The firm replied giving the method of preparation of the product. However, since no details were given as to the method used to "debitter" the cascara, one cannot say how much of the active principle of cascara was lost in the process of preparation and therefore the amount of cascara in a given quantity of the finished product cannot be judged. Experiments carried out lead to the conclusion that "Cascara-Agar" contains at most only a trace of cascara, and that it is misleading to call the preparation "Cascara-Agar." Information was received that the Reinschild Chemical Co. still markets "Regulin," a product which has been stated to be prepared in the same manner as is "Cascara-Agar." Since the Council does not accept an article under one name if an essentially similar product is marketed by the same firm under another name, this makes "Cascara-Agar" further objectionable. The Council declared "Cascara-Agar" unacceptable because it is an indefinite mixture marketed under a misleading name with unwarranted therapeutic claims, and because an essentially similar product is marketed by the same firm under another name. (Jour. A. M. A., October 26, 1929, p. 1309.)

ANAYODIN NOT ACCEPTABLE FOR N. N. R.

The Council on Pharmacy and Chemistry reports that Anayodin was presented by the Ernst Bischoff Co., Inc., with the statement that it was composed of iodoxyquinolin-sulphonic acid with the addition of 22 per cent sodium bicarbonate, and that from the information before the Council it appeared that Anayodin was a mixture prepared from approximately four parts of 7-iodo-8-hydroxy-quinolin-5-sulphonic acid and one part of sodium bicarbonate, which during recent years has been used in the treatment of amebic dysentery while similar preparations under various trade names had before this been proposed as wound antiseptics. The Council informed the Ernst Bischoff Co., Inc., that, since it was not the discoverer of the preparation, the Council could not recognize a proprietary name for it, but, unless other conflicts appeared, its product would be accepted if marketed as chiniofon, which name the Council had adopted for the mixture represented by "Anayodin," if acceptable tests were provided to insure its purity and uniformity and the advertising revised to meet stated objections. Ernst Bischoff Co., Inc., did not make its preparation acceptable and, accordingly, the Council declared "Anayodin" unacceptable for New and Non-official Remedies because it is an unoriginal preparation, marketed under a non-informing name without an adequate statement of composition; because no evidence was available to show that its identity and uniformity are adequately controlled; and because it is marketed with therapeutic claims which are unwarranted. (Jour. A. M. A., October 5, 1929, p. 1065.)

A PAGE FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

How Shall the Doctor Be Paid?

An important current magazine devotes its entire issue to this timely subject and every medical man should find something of interest to him in the discussion. The vexing question of the cost of health is discussed from the angle of the physician, of the economist, the business man, the public health expert and a large number of others who have interesting things to say on the ways and means of extending that commodity as far as possible at a proper cost in the January *Survey Graphic*.

Few of these experts are able to do more than offer pertinent observations. The answer to the problem of medical costs which are at once fair to the purchaser and to the doctor is apparently quite too complicated for any one man's solution. However, here are a few pertinent quotations from these entirely unacrimonious discussions, all of which are illuminating if not conclusive.

"Health is quite as much a social as a personal necessity and if this is admitted there is no dodging the individual and collective privilege and hence duty of attaining as much of it as the medical and social sciences have to offer. Knowledge, indeed, is pooled but its distribution for use is much after the fashion of April showers. It is time the users tapped the pool with a strong sky scraping plan of living." Thus Dr. Haven Emerson, health editor of the *Survey Graphic* and professor of Preventive Medicine, Columbia University, in a somewhat figurative flight which serves as introduction to the survey.

"If, as is generally supposed, doctors' fees are a preponderating item in making adequate care impossible," says Dr. George Edward Follansbee, chairman of the Judicial Committee, American Medical Association, "it would follow that a vast sum is flowing into the pockets of the medical profession. . . . Each doctor knows comparatively and probably closely the incomes of his fellow practitioners. His guess is that the income of a large portion of the profession will average in the neighborhood of $5,000 to $6,000 a year. An income of $5,000 to $6,000 a year does not appear to be excessive for a man who has spent his life up to 28 years of age in study and preparation and some $12,000 in expense before he begins earning."

Walton H. Hamilton of the Yale Law faculty, writing as economist, patient and parent, takes up the discussion at this point. "The technology of medicine has advanced," he remarks. "Its organization has lagged. . . . The problem of mending our arrangements so that the ordinary man has a real chance at adequate service and at a tolerable cost needs to be attacked in the way disease is attacked. The right answer is probably that there is no right answer. In the spirit of constructive inquiry we can only seek the rightest answer we can find."

"Only the well-to-do and the dependent in Columbus [Ohio] have the medical care at child-birth approximating modern standards" is the conclusion of Mary Louise Mark of the Ohio State University faculty who inquired into and analyzed the costs and service to 540 "run-of-the-mill" babies in Columbus. "The very poor and the lower range of those classified as intermediate have far from satisfactory care. The more intelligent of the parents in close circumstances are the chief sufferers because they are conscious of the risks involved for both mothers and babies."

"Any business which is organized in such a way as to discourage the masses from becoming customers is not on a solid economic basis no matter how excellent its scientific attainment may be," observes Edward A. Filene, who, as president of William Filene's Sons Company of Boston, has brilliantly demonstrated his knowledge of successful business.

"The health department can help the doctor increase his legitimate private practice through its program in diphtheria immunization, for instance," declares Dr. Shirley W. Wynne, New York City's Commissioner of Health. "But the doctor must remember that once a health department embarks upon a program to encourage people to go to a private practitioner he must do his part to keep that patient by his professional competence, moderate charges and effective follow-up work."

The industrial hospital, the pay clinic, certain Canadian experiments in sickness insurance and outlines of the work of the foundations to fight disease also occupy pages of the survey.

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 10:15 o'clock every Wednesday morning over Station WCCO, Minneapolis and St. Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of March will be as follows:

March 5—"High Blood Pressure"
March 12—"Self Medication"
March 19—"Bronchitis"
March 26—"Paralysis of Face"

MINNESOTA STATE MEDICAL ASSOCIATION

Plans for the program of the annual meeting of the Minnesota State Medical Association to be held in Duluth July 14, 15 and 16, are well under way.

The symposia on traumatic surgery, immunology, cancer, rheumatic fever, anesthesia and therapy suggested as program headliners by the program committee have been approved by a majority of association members. The interesting and important aspects of each are accordingly being apportioned to the three days' sessions with the most distinguished men available to lead discussion and demonstration. Among the latter is Dr. Homer F. Swift, New York, who has been asked to discuss rheumatic fever.

Interesting and unusual entertainment is also being arranged for wives of members who attend.

UNITED STATES PHARMACOPŒAL CONVENTION

The eleventh decennial United States Pharmacopœal Convention will convene in Washington, D. C., May 13, 1930. Eligible organizations and colleges should obtain credential blanks from the Secretary of the Convention, Lyman F. Kebler, M.D., 1322 Park Road, N. W., Washington, D. C. Organizations entitled to representation at the convention include Medical Schools, State Medical Associations, and the American Medical Association.

UPPER MISSISSIPPI MEDICAL SOCIETY

The annual meeting of Upper Mississippi Medical Society was held Jan. 30, 1930, at Brainerd, Minnesota, Dr. T. C. Davis presiding. Minutes of the previous meeting were read and approved.

The annual financial statement showing a certificate of deposit of $446.49 and balance in checking account of $493.36—total cash on hand $939.85—was read and accepted.

The Board of Censors reported favorably on the application of Dr. Knute Holmgren, Upsala, Minn. It was moved, seconded and carried that the rules be suspended and the secretary cast the unanimous ballot for Dr. Holmgren, who was thereby declared duly elected to membership in the Upper Mississippi Medical Society.

Meeting places were selected for the year 1930 as follows: Spring meeting, Wadena; summer meeting, International Falls, preferaby during the month of July; fall meeting to be arranged if possible in joint session with the Stearns-Benton County Society, the place of meeting and time to be decided by the presidents and secretaries of the two societies.

Officers elected for the ensuing year are: President, Dr. G. I. Badeaux, Brainerd; First Vice-president, Dr. W. A. Miller, New York Mills; Second Vice-president, Dr. A. F. Gaalaas, Wadena; Secretary, Dr. F. F. Kumm, Wadena. Dr. J. A. Thabes and Dr. J. S. Grogan were elected delegates to the state meeting, with Dr. B. W. Kelly and Dr. F. F. Kumm as alternates. Dr. J. A. Thabes was re-elected censor for a period of three years.

The following resolution was adopted: Inasmuch as it is reported that there is at the present time in some parts of the State a desire to reduce the State dues, be it hereby resolved that it is the sentiment of the Upper Mississippi Medical Society that the State Association has done efficient work in the past few years and that this has been made possible by the increased dues; that any reduction in dues would be detrimental to the efficiency of the Society and that our delegates be so instructed and that a copy of this resolution be sent to the State Secretary.

The scientific program included the following presentations:

Treatment of Vomiting of Pregnancy
Dr. Milton G. Brown, Brainerd

Present Method of Treatment of Tuberculosis
Dr. F. F. Kumm, Supt. Fair Oaks San., Wadena

An Informal Surgical Discussion with Lantern Slides
Dr. Harry Ritchie, St. Paul

The Effects of Sun in the Prevention and Treatment of Disease
Dr. W. R. Ramsey, St. Paul

Discussion of State Problems
Dr. S. H. Boyer, President of Minnesota State Medical Society, Duluth

Moving Pictures
Surgical Treatment of Peptic Ulcers
(Davis & Geck)

Resolutions thanking the doctors appearing on the program were passed by the society.

The meeting adjourned.

G. I. Badeaux,
Secretary.

RICE COUNTY MEDICAL SOCIETY

A meeting of the Rice County Medical Society in conjunction with the Auxiliary, Nurses and Doctors' wives, was held February 6 at the State School for the Feeble Minded at Faribault. Dinner was served at 6:30 p. m. in the Main building under the auspices of Dr. and Mrs. Murdoch.

Dr. George Earl, Saint Paul, presented two subjects: (1) "Surgical Indications (non-thoracic) in the Minimal Tuberculosis Patients" and (2) "Economic Changes in the Practice of Medicine." Response on the part of members was led by Dr. W. D. Beadie, superintendent, Cannon Falls Sanitarium, and Dr. D. E. McBroom, superintendent at Cambridge.

Dr. W. E. Wilson of Northfield expressed appreciation and thanks to Dr. and Mrs. Murdoch for their generous hospitality in behalf of the society. Dr. Murdoch in turn expressed hearty appreciation to Dr. Earl for his instructive and interesting talk.

Mrs. Adolph M. Hanson, in the absence of Dr. Hanson, expressed gratitude and appreciation for the friendly attitude and assistance accorded Dr. Hanson in his research work on Karkinolysin for the treatment of malignancy, by the members of Rice County Medical Society and others.

Mrs. M. L. Mayland, Secretary of the Auxiliary, briefly outlined the aims and objects of her society.

Dr. Norman Lende, Faribault, was unanimously elected to membership.

C. J. Plonske,
Secretary.

OF GENERAL INTEREST

Dr. Clyde H. Fredrickson, formerly of the Mayo Clinic, Rochester, where he held a surgical fellowship, is now associated with the Great Falls Clinic, Great Falls, Montana.

Dr. Mary C. Ghostley of International Falls will act as superintendent of the Lake Julia Tuberculosis Sanatorium, Puposky, Minnesota, in the absence of Dr. R. L. Laney, who is taking a year's vacation.

Dr. Frederick W. Schlutz of Minneapolis, for sixteen years associated with the University of Minnesota Medical School and since 1924 Professor of Pediatrics, will move to Chicago about April 1st to become Professor of Pediatrics at the newly formed Department of Pediatrics at the University of Chicago.

The Secretary of the Minnesota State Medical Association announces that the American Commission of the International Hygiene Congresses invites us to send a representative to the word health sessions to be held in Dresden May 15 to September 30, 1930. If there is anyone expecting to be in Dresden, or if there is anyone who wishes to make the trip, which will cost $774, application should be sent to Dr. E. A. Meyerding, 11 West Summit Avenue, Saint Paul.

Dr. Leland S. Fuller of Chicago has joined the Morsman Eye, Ear, Nose and Throat Clinic of Hibbing and Virginia. Dr. Fuller comes from Cook County Hospital, where he has recently completed a service in the eye, ear, nose and throat department. He is a graduate of Rush Medical College. The personnel of the Morsman Clinic is now as follows: L. W. Morsman, M.D., Fred McK. Ruby, M.D., Andrew Sinamark, M.D., and L. S. Fuller, M.D.

A gold medal will be given to the best scientific exhibit submitted by any single individual at the Annual Meeting of the Minnesota State Medical Association in Duluth, July 14, 15 and 16.

This is the first award of the sort ever given. Its object is to encourage private participation in exhibits and it is the gift of the Southern Minnesota Medical Association, which proposes to use the surplus in its treasury for the purpose.

Dr. Owen Wangensteen was appointed chief of the Department of Surgery at the University of Minnesota Medical School, January 1, 1930. Dr. Wangensteen received his B.A. degree in 1919 and his M.D. in 1922. In 1925 he received his Ph.D. degree after three years' work in Medicine on the campus and at Rochester, Minnesota. Upon the resignation of Dr. Arthur Strachauer as chief of the surgical department in 1925, Dr. Wangensteen was selected to succeed Dr. Strachauer and availed himself of the opportunity to pursue special studies here and abroad in preparation for his present position. He studied in Europe between August, 1927, and September, 1928, under Dr. Fritz de Quervain at Berne, Switzerland, and in the physiological laboratory there, under Dr. Leon Asher, in addition to visiting numerous medical centers in Europe.

Sixty officers, chairmen and committee members of the Minnesota State Medical Association attended a meeting called by President S. H. Boyer for the purpose of coördinating association activities at the Leamington Hotel, Minneapolis, February 10.

"Attendance and interest displayed at this meeting were more than satisfactory," Dr. Boyer declared. It was the first meeting of the sort in the history of the Association.

A plan for an extension course particularly impressed the meeting. It is to include evening programs of the Minnesota Public Health Association; serum and vaccine therapy, heart disease, the State Board of Health, subjects of scientific interest, such as dermatology and lectures, to be provided by the Extension Division of the University of Minnesota.

A similar meeting of the chairmen will be called by Dr. Boyer this spring.

NEW AND NON-OFFICIAL REMEDIES

The following articles have been accepted by the Council on Pharmacy and Chemistry.

ABBOTT LABORATORIES, INC.

Butesin Picrate Eye Ointment

LAKESIDE LABORATORIES, INC.

Ampoules Dextrose (d-Glucose) 10 Gm., 20 cc.

Ampoule No. 51 Sodium Cacodylate 0.243 Gm. (3¾ grains), 5 c.c.

H. K. MULFORD CO.

Pneumococcus Antibody Solution, Types I, II and III Combined-Mulford, four 50 c.c. double-ended vials.

The following articles have been exempted and included with the List of Exempted Medicinal Articles (New and Non-official Remedies, 1929, p. 481):

DAVIES, ROSE & CO., LTD.

Pil. Digitalis (Davies, Rose)

KINGS COUNTY PACKING CO.

Sac-A-Rin Brand California Bartlett Pears

Sac-A-Rin Brand California Tidbits Hawaiian Pineapple

Sac-A-Rin Brand California Royal Anne Cherries

LAKESIDE LABORATORIES, INC.

Ampoule No. 64 Calcium Chloride 10%

TRUTH ABOUT MEDICINES

Diphtheria Toxoid-National.—A diphtheria toxoid (New and Non-official Remedies, 1929, p. 368) prepared from seven-day cultures of the diphtheria bacillus that yield a toxin having an L+ dose of not less than 0.25 c.c. The toxin is treated with formaldehyde. The finished product is tested for antigenic potency. The product is marketed in packages of three vials (one immunization treatment); in packages of one vial (fifteen immunization treatments); packages of forty-five vials (fifteen immunization treatments). The National Drug Co., Philadelphia.

Scarlet Fever Streptococcus Antitoxin-Cutter.—A scarlet fever streptococcus antitoxin (New and Non-official Remedies, 1929, p. 350) prepared by the method of Drs. Dick by license of the Scarlet Fever Committee, Inc. It is marketed in packages of one syringe containing 2,000 units, and in packages of one syringe containing 6,000 units. Cutter Laboratory, Berkeley, Calif.

Typho-Bacterin Mixed (Triple Vaccine TAB).—This product (New and Non-official Remedies, 1929, p. 380) is also marketed in packages of thirty 1 c.c. vials, being ten immunizations of three doses each. H. K. Mulford Co., Philadelphia. (Jour. A. M. A., January 4, 1930, p. 31.)

Ampules Sodium Cacodylate-Mulford, ¾ grain, 1 c.c.—Each ampule contains sodium carcodylate (New and Non-official Remedies, 1929, p. 73) 0.05 Gm. (¾ grain) in c.c. of sterile solution, with 1 per cent of benzyl alcohol. H. K. Mulford Co., Philadelphia.

Ampules Sodium Cacodylate-Mulford, 3 grains, 1 c.c.—Each ampule contains sodium cacodylate (New and Non-official Remedies, 1929, p. 73) 0.2 Gm. (3 grains) in 1 c.c. of sterile solution, with 1 per cent of benzyl alcohol. H. K. Mulford Co., Philadelphia.

Ampules Sodium Cacodylate-Mulford, 5 grains, 1 c.c.—Each ampule contains sodium cacodylate (New and Non-official Remedies, 1929, p. 73) 0.32 Gm. (5 grains) in 1 c.c. of sterile solution, with 1 per cent of benzyl alcohol. H. K. Mulford Co., Philadelphia.

Erysipelas Streptococcus Antitoxin (Concentrated)-Mulford.—This product (New and Non-official Remedies, 1929, p. 349) is also marketed in packages of one 10 c.c. syringe containing 500,000 protective units. H. K. Mulford Co., Philadelphia. (Jour. A. M. A., January 11, 1930, p. 105.)

Curdolac Casein-Bran Improved Flour.—A flour prepared from casein, carbohydrate-free bran, and soya bean, to which leavening and flavoring have been added. It may be used for the preparation of muffins or bread having a comparatively low carbohydrate content and low food value, with bulk. Curdolac Food Co., Waukesha, Wis.

Curdolac Soya-Bran Flour.—A flour prepared from soya bean and a starch-free bran with a leavening mixture. It may be used for the preparation of bread and muffins for use in diets in which a comparatively low carbohydrate content is desired. Curdolac Food Co., Waukesha, Wis.

Curdolac Breakfast Cereal.—A medicinal food prepared from soya beans blended with wheat products, including starch-free bran. It may be used as a hot food in diets in which a comparatively low carbohydrate content is desired. Curdolac Food Co., Waukesha, Wis.

Curdolac Casein Compound.—A flour prepared from casein, vegetable fiber and a leavening mixture to which sodium chloride and gluside are added. It may be used for the preparation of carbohydrate-free bread, muffins, cake, etc., for use in diets in which a relatively low carbohydrate content is desired. Curdolac Food Co., Waukesha, Wis.

Curdolac Soya Flour.—A flour prepared from the soya bean. It may be used for the preparation of foods in diets in which a relatively low carbohydrate content is desired. Curdolac Food Co., Waukesha, Wis.

Curdolac Wheat-Soya Flour.—A flour prepared from soya beans, starch-free bran and a small proportion of wheat, with leavening and flavoring. It may be used for the preparation of muffins, cakes, waffles, etc., of well balanced food value for use in restricted diets. Curdolac Food Co., Waukesha, Wis.

Curdolac Soya-Cereal Johnny Cake Flour.—A flour prepared from soya beans and cereal products to which leavening and flavoring have been added. It may be used in the preparation of muffins, cakes, waffles, etc., for use in diets relatively low in carbohydrate, designed for those who cannot use products made with bran. Curdolac Food Co., Waukesha, Wis.

Curdolac Soya-Bran Breakfast Food.—A medicinal food prepared from soya beans and a starch-free bran, to which has been added leavening, flavoring, gluside, and oils without food value. It may be used in diets in which a low carbohydrate content is desired. Curdolac Food Co., Waukesha, Wis. (Jour. A. M. A., January 18, 1930, p. 185.)

CONSULTATION BUREAU

Wm. A. O'Brien, M.D., *Director*
Minnesota State Medical Association
11 West Summit Avenue
Saint Paul, Minnesota

1. *Question.*—I have a patient, forty-two years old, with a lump in the breast. I wish to know how to make a biopsy, and what the diagnostic possibilities are.

Answer.—The indications for a biopsy of a lump in the breast in a woman past thirty years of age are very definite. While attachment to the skin with dimpling and retraction of the nipple are suggestive of malignancy, no absolute diagnosis can be made without removing the entire mass. Many malignant tumors are not attached to the skin nor do they show retraction of the nipple. While the consistence of the mass on palpation is helpful, very hard tumors are sometimes proven to be benign on biopsy. The presence or absence of enlargement of the lymph nodes in the axilla is not helpful because they may be enlarged from another cause.

The ideal method for preparation for a biopsy is to get the patient ready for a radical resection of the entire breast and axillary contents. The skin should be prepared in the usual way, and the axilla shaved. Many surgeons use local anesthesia to remove lumps which they believe to be benign, so that if there is any delay in getting the report no time is lost with a general anesthesia. We will assume that the lump can be removed under local anesthesia. Infiltration with novocain can be done, and the entire mass excised. In no instance should the lump be cut into before removal. After the mass and surrounding tissue have been removed, it is advisable for the surgeon to make an incision through the tumor. In 95 per cent of the cases, a diagnosis can be made on the gross appearance. If the tumor is very hard and shows no definite border, it is probably malignant. If in addition, the surface is concave and there are multiple yellowish points present, it is malignant. In only 5 per cent of the cases is it necessary to resort to the frozen section. Many mistakes are made on rapidly made frozen sections, and it has been found advisable to rely on the gross appearance. If the mass is a fibroadenoma, it may be recognized by the sharp border. A definite capsule is present. When a fibroadenoma is incised, the edges bulge because the tumor is growing under pressure in a limited area. The surface of fibroadenomata varies from hard structures to the soft appearance of a rapidly growing tumor. Rapidly growing tumors are often found in conjunction with pregnancy or lactation. Cystic disease has a variable appearance. Sometimes there is nothing more than a diffuse induration which is not hard in which may be found either small or large cysts. Sometimes these masses prove to be a single cyst filled with fluid under pressure. Traumatic fat necrosis also gives a similar appearance to malignancy grossly, but the characteristic signs of a malignant tumor are absent. On section, fat necrosis shows definite changes which are very characteristic. If the mass is due to tuberculosis, a similar change, characteristic of the disease, will be found in the frozen section.

When a diagnosis of carcinoma is made, there is only one treatment to be done, providing metastases have not been demonstrated elsewhere before the biopsy is made. It is always wise to search the supraclavicular space and to do an *x*-ray of the chest in suspected cases. Only radical breast amputations should be done if the tumor has not extended beyond the breast and axillary contents. There is no known way of making an accurate clinical diagnosis. The practice of waiting to see what will happen to a lump in the breast is very bad. Many women have lost their only chance by local treatment.

2. *Question.*—Please give me the main points in the diagnosis and treatment of gas gangrene.

Answer.—Gas gangrene is a condition found in certain kinds of wounds, and is characterized by rapid spread, extensive destruction of tissue, foul discharge, and the formation of gas in the tissues. It always occurs secondarily to a wound. The odor is of a very peculiar, pungent quality, and once smelled is never forgotten. A characteristic finding is a sensation of crepitus in the tissue. The extent of the process can also be confirmed by an *x*-ray of the affected part. When opened, the muscles show a definite, dark, reddish brown discoloration and do not contract when stimulated. From 80 to 90 per cent of all cases are due to the bacillus welchii.

An antitoxin has been known since 1917. It is an antitoxic serum prepared from the blood plasma of horses, highly immunized against the toxin of bacillus perfringens or bacillus welchii. It may be purchased under the name perfringens antitoxin. For prophylaxis, 25 units are used. For treatment, an initial dose varies from 40 to 100 units, given intramuscularly followed by 40 units intravenously. From 40 to 80 units intramuscularly are given each day thereafter as indicated. The bacillus welchii is found in the intestinal tract of nearly all adults and about 40 per cent infants under one year of age. It forms spores under certain conditions and is liable to live in soil for a considerable time. It is possible to develop human infections from soil contaminated with human excreta. After the antitoxin is given, it is advisable to trim away all necrotic tissue and irrigate the wound with Dakin's solution. The use of hydrogen peroxide packs and irrigations is also recommended. If an extremity is involved, amputation is usually done. Gas gangrene, if it is not treated, practically always terminates fatally in from forty-eight to seventy-two hours. The condition must be recognized early and the proper treatment done at once. Favorable statistics were compiled during the war, and the evidence in favor of serum has grown since. The antitoxin may be purchased in three strengths, which includes the double strength and the concentrated preparation. Tetanus must also be kept in mind with these wounds, and many investigators use both sera in badly infected cases.

OBITUARY

Louis M. Benepe
(1862-1930)

Dr. Louis M. Benepe of Saint Paul died at his home February 14, 1930, after an illness of five months. He was 67 years of age and had practiced in Saint Paul for forty-two years.

Dr. Benepe was born in Columbia, Missouri, October 27, 1862. He was a graduate of Valparaiso University in Valparaiso, Indiana, and obtained his medical degree at Missouri Medical College in Saint Louis. He came to Saint Paul in 1888.

Dr. Benepe had been a member of the Ramsey County Medical Society since 1891, and had also been on the medical staffs of the Ancker, St. Joseph's and St. Luke's hospitals. He was also a member of the Triune Lodge, Knights of Pythias, and of the Damascus Commandery, Osman Temple of the Shrine.

Dr. Benepe is survived by his widow, Mrs. Leila A. Benepe; five daughters, Ruth and Alice Benepe, Mrs. Helen Vandersloot, Mrs. D. L. Cummings, all of Saint Paul, and Mrs. Frank Munoz of Wichita, Kansas; three sons, Dr. Louis M. Benepe, Jr., of Saint Paul, Dr. James L. Benepe of Dent, Minnesota, and R. S. Benepe of New York City. One brother, Dr. John Benepe of Anderson, Indiana, also survives him.

Paul Burns Cook
(1877-1930)

Dr. Paul B. Cook, well known specialist in urology and dermatology, of Saint Paul, died February 9, 1930, at Miami Beach, Florida. Dr. Cook had practiced in Saint Paul for over twenty-five years and since 1919 had been associated in the practice of his specialty with Dr. Charles Freeman.

Born in Rochester, Minnesota, the son of George Clinton and Elizabeth Burns Cook, on February 17, 1877, Dr. Cook obtained his M.D. degree at the University of Minnesota in 1900. He joined the Ramsey County Medical Society in 1902, was vice president of the Society in 1906, and in 1907 spent a year studying abroad, spending most of the time in Vienna. In 1911 and 1912 he acted as Assistant Health Commissioner and instituted valuable methods in the administration of the office.

Dr. Cook was one of the first medical men in Saint Paul to enlist, and after preliminary training at Fort Riley and serving at Camp Funston, he went abroad as Major in the 88th Division. Fond of travel, the foreign shores visited by Dr. Cook included Hawaii, another trip to Vienna in 1917, a world tour two years ago and last year a vacation spent in Africa.

Besides being a member of the Ramsey County Medical Society, Dr. Cook was also a member of the Minnesota Academy of Medicine and the Minnesota State Urological Society. He also belonged to the Town and Country Club, Somerset Golf Club, the Minnesota and University Clubs.

Dr. Cook is survived by two sisters, Mrs. Frank B. Kellogg and Mrs. Frank J. Ottis of Saint Paul, and a brother, George Cook of Rochester.

Henry F. Hoyt
(1854-1930)

Dr. Henry F. Hoyt, formerly a resident of Saint Paul but for the past twenty years living at Long Beach, California, died at Yokohama, Jan. 21, 1930, while en route from Manila.

Dr. Hoyt's long life of various activities has been depicted in his autobiography published last summer under the title "A Frontier Doctor," the introduction of which was written by former Secretary of State Frank B. Kellogg.

Dr. Hoyt's parents came to Saint Paul in 1848 and settled on a farm near Snelling and Larpenteur Avenues. Here the doctor was born Jan. 30, 1854.

At the age of eighteen Dr. Hoyt accompanied the expedition that established the boundary line between the United States and Canada from Glyndon, Minnesota, to Pembina, North Dakota. Returning to Saint Paul a year later he took up the study of medicine in the office of Dr. J. H. Murphy and in 1875 was placed in charge of the Church Hospital, now St. Luke's. He later entered Rush Medical College, where he received his degree.

Upon graduation Dr. Hoyt began practice in Deadwood, South Dakota. According to his own story undertakers were more needed there than doctors so he journeyed to the Texas Panhandle country on the strength of a report that an epidemic of smallpox was raging there. For the next twenty years he was, in turn, doctor, cowboy, miner, vigilante and doctor again. In Texas he became well known as a sprinter and boxer. From 1893 to 1898 he was chief surgeon for the Great Northern railway.

When the Spanish-American war broke out Dr. Hoyt entered the service and eventually became the ranking Army surgeon in the Philippines under General Frederick D. Grant. In this capacity he was in twenty-five engagements and at Marilao, Luzon, received two flesh wounds but stayed on duty. For this he was cited for bravery twenty-five years later.

Retiring to Saint Paul after the war, Dr. Hoyt became city health commissioner. Last fall, he and a sister, Mrs. George Wilson, of Minneapolis, sailed for the Philippines in order to spend Christmas with a sister, Mrs. George Harvey, of Manila. On board the ship Dr. Hoyt had the unique experience of hearing a review of his own book, "A Frontier Doctor," broadcast by radio from San Francisco.

Besides his sisters, Dr. Hoyt is survived by one son, John Terrell Hoyt, and a stepson, Owen H. Gray.

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of January 8, 1930

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, January 8, 1930. Dinner was served at 7 p. m. and the meeting was called to order at 8 p. m. by the Vice-president, Dr. J. S. Gilfillan, of St. Paul. There were 32 members present.

Minutes of the December meeting were read and approved.

The Secretary read a letter from Dr. Gustav Schwyzer of Minneapolis, resigning as President of the Academy. A motion was carried that Dr. Schwyzer's resignation be accepted and the Academy proceed to ballot for another president. Dr. Emil Geist, Minneapolis, was unanimously elected President for the year 1930.

Dr. Arnold Schwyzer (St. Paul) reported the following case* of Endothelioma of the Pleura removed by operation. Specimen was shown.

This morning we had an unusual operation on a young man, 23 years old, who had noticed a persistent pain in the right side of his chest for two years. *X*-rays made several times during the last year showed a tumor originally the size of a large plum gradually growing larger, apparently in the periphery of the lung. A bulging was noticed in November and biopsy showed endothelioma. First we resected a rib above and one below the bulging area, that is, about 12 cm. of the sixth and eight ribs. It was done under moderate over-pressure. The tumor was adherent to the diaphragm. This area of the diaphragm was excised, and a tight closure of the wound was made. This evening, 8 hours after the operation, the patient is reported doing well.

Neither Sauerbruch nor Lilienthal reports an operation for endothelioma of the pleura in their books on surgery of the chest.

(Addendum: Recovery was very smooth. The patient was out of bed four days after the operation and left the hospital one week after operation, feeling well.)

DISCUSSION

Dr. E. T. Bell (Minneapolis): This is a most unusual tumor and we have never had anything like it in our experience in the laboratory. The biopsy shows it pretty clearly to be an endothelioma. It is a cystic circumscribed tumor attached to the pleura over the ribs. The operation was much simpler than had been anticipated. It is the only case on record, I think, of an endothelioma that has been operated upon successfully. I am inclined to think it will be cured because it does not seem to involve any surrounding tissues.

Dr. J. S. Gilfillan (St. Paul): About 25 years ago I had a case come to me with a tumor just over the heart. We did not have *x*-ray then and we did not have available any pressure apparatus. At first I thought that in order to prevent the collapse of the lung I might pass large needles with sutures and get at the lung and hold it, but I did not do that. I opened the chest and found the tumor had involved the left lung. I excised four ribs with the tumor and lifted the lobe of the lung out and excised about one-half of the lung. I rotated the remaining portion of the lung and sewed it around the opening and closed the opening. There was apparently no shock from the operation and the patient felt fine the next day. That was an endothelioma; it was wider and flatter than Dr. Schwyzer's. About a year later I saw the patient, and at that time he had metastases in the vertebræ.

Dr. Herbert Jones (Minneapolis): About two years ago I had a man come to see me complaining of pain in his right shoulder. I went over him for possible trouble in the cervical nerves, a lung condition, or aneurysm, and they seemed to be all negative. I could not make a diagnosis. He did not seem to be getting any results and left me and went to one of the clinics and they *x*-rayed him and found a pleural effusion. They tapped him, and after that his pain was much worse. He then went to an osteopath and later came back to me, this last fall. He died October 30, 1929. When he returned to me he presented the appearance of a large tumor of the chest, but he was in such bad shape that I did not do anything but try and keep him comfortable. He had had one son die of Hodgkin's disease, and a daughter has tuberculosis. I will read parts of the pathological report from the University of Minnesota:

"The right diaphragm is very firm and rigid. The left pleural cavity contains 200 c.c. of straw-colored fluid. The right cavity is obliterated by firm white tumor tissue except for two pockets of straw-colored fluid of about 200 c.c. each, which are located posteriorly. The pericardial sac contains about 20 c.c. of slightly cloudy fluid. The right side of the sac is injected and roughened from extension of the tumor tissue. The right lung is firmly adherent to the chest wall, the diaphragm and the mediastinum by a firm white growth of tumor tissue up to 3.5 cm. in thickness. This growth has gone through the right diaphragm and is adherent to the liver. The nodes of the bronchi are normal to inspection.

"The spleen weighs 90 grams. The diaphragmatic surface of the spleen is firmly adherent to the diaphragm by a small firm white growth 3 cm. across. On section there are many small healed miliary tubercles.

"The liver weighs 1,100 grams. It shows moderate evidence of chronic passive congestion and is firmly adherent to the diaphragm by firm white tumor tissue. The gallbladder contains two small stones.

"Diagnosis: Endothelioma of the pleura with extension to liver, pericardium, lung, diaphragm and spleen."

I was absolutely unable to make a diagnosis in that case, and no opportunity for biopsy presented itself as in Dr. Schwyzer's case. Although I have had autopsies of a large per cent of my cases, I have never before had a case of endothelioma of the pleura and do not see how I could diagnose another.

*Case to be published in full at later date.

Dr. Hilding Berglund (Minneapolis): A moment's consideration of the diagnosis might be worth while. Could the diagnosis have been made a year ago? I believe not. A circumscribed endothelioma of this configuration is such a rarity that the possibility would certainly not be considered without biopsy. The mass was too well circumscribed and rounded to fit in with a carcinoma of the lung of the solid block type. The picture could just as well have indicated a cyst or an encapsulated empyema. I believe a needle was inserted in the mass about a year ago and about 10 c.c. of clear fluid, not further described, were obtained. With nothing but these facts to go by, I do not believe any very aggressive action was indicated at that time. Now the diagnosis was made possible only through the bulging of the tumor between the ribs and the result of the biopsy was a surprise. It is gratifying to think that the patient was no worse off today than he would have been if it had been possible to decide about an operation a year ago.

One diagnostic procedure, which often proves of value in cases of this type, should be mentioned: a pneumothorax performed before an operation. With the collapse of the lung new possibilities offer themselves for *x*-ray differentiation between intra- and extrapulmonary tumors. Adhesions in one direction or other likewise present themselves. Jacobaeus and Key used to be very fond of this procedure before operation, but of course it is not always necessary.

Dr. Schwyzer (St. Paul): If we had made a preliminary diagnostic pneumothorax we would have had the lung fall away entirely from the growth and we could then have gone in with more assurance of success. However, even if otherwise, it would not have changed our decision to explore; and as a part was adherent to the diaphragm by soft friable neoplastic tissue, it would probably have been torn off and given a chance for dissemination in the pleura.

Dr. Gilfillan's case is the only one that I have heard of that was operated on. I looked through several books rather hurriedly this afternoon and could not find a case.

I forgot to mention the fact that a year ago there was some fluid taken away from this growth.

The sensible thing to do, after the wound is healed, will be raying the area. We shall probably use radium, very strongly filtered so that the skin will not be damaged. I have a case in the hospital now who, a year ago, had had a little over 7,000 mg. hours in one session after an operation of an acousticus tumor in the cerebellopontine angle. No hair fell out after that application. She is in the hospital again now and getting this time 6,000 mg. hours.

Dr. Zimmermann (St. Paul): I would like to ask Dr. Schwyzer how he could do this without positive pressure?

Dr. Schwyzer: We used positive pressure. It was done in the simplest way. The patient was getting oxygen all the time through tubes put into the nose, with about 20 cm. water pressure. The patient did not have his mouth closed; there was just a little extra oxygen and a little extra pressure. I could have steadied the mediastinum by getting hold of the lung with a probang or we could have increased the oxygen pressure and ballooned the lung, but it was not necessary, and thus we had good room to work in with the lung almost collapsed. With the spinal anesthesia the patient was breathing very quietly. If there had been any difficulty I could have had more pressure by holding the patient's mouth closed or by increasing the pressure, or both. If the tumor had been adherent to the lung, and knowing it had a clear outline into the lung, I could very readily have divided the lung tissue between clamps and sewed it after the resection. I would have done just what Dr. Gilfillan did in his case where he had such a fine surgical result.

Dr. C. Naumann McCloud (St. Paul), retiring President, then read his Presidential Address entitled "Essential Hypertension," and asked for discussion from the members.

Dr. McCloud: Before presenting my paper, I wish to thank the Society for the honor shown me in electing me President of the Academy, where I have served during the past 15 months. It has been a very enjoyable year, and I particularly want to thank the members of the Executive Committee; they have been of very great help to me in conducting the proceedings of the organization, and in revising and putting in force the new Constitution. May I also state that our past Secretary, Dr. Carl Drake, has rendered a great deal of assistance to me, and I am sure that with the new efficient Secretary and the incoming officers, we should have a very profitable year before us.

I am very much interested in the subject of medical selection in connection with life insurance, and as the subject of hypertension has been causing us a great deal of perplexity, I thought this subject might be presented to the Academy tonight. In looking up the literature I was surprised to find how little there was published on the subject, and, though the President's address is not usually open for discussion, as there are several authorities on the subject of blood pressure here this evening, I would be very glad to have my paper discussed.

DISCUSSION

Dr. H. T. Nippert (St. Paul): I would like to ask the Doctor about the normal diastolic pressure according to different ages; for instance, what is considered the normal diastolic pressure between 20 and 30 years and between 30 and 40, and so on.

Dr. McCloud: Speaking generally for life insurance companies, it would fluctuate, but it would vary 8 to 12 points above the average.

Dr. E. L. Gardner (Minneapolis): Dr. Bell's statistics on autopsied cases may place the percentage of cardiac deaths in hypertension rather high. In my experience, relatives object to postmortem examinations where the head is to be examined, and this may make the number of cerebral cases which are autopsied relatively much lower than those of cardiac failure.

Dr. McCloud: This is the experience of all medical directors, that they look upon the cause of death with a good deal of misgiving in a good many of these cases. For instance, just yesterday a man died a sud-

den death and the attending physician gave the cause of death as "edema of the lungs." From all symptoms it was coronary thrombosis, and the autopsy confirmed this diagnosis.

I would like very much to have Dr. Bell, for he can so beautifully do it, discuss the subject brought up by Dr. Gardner.

Dr. E. T. Bell (Minneapolis): I am very much interested in Dr. McCloud's paper. The diastolic pressure has not been given as much attention as it deserves. I have not made much use of it in my studies because there seemed to be so much variation and irregularity that it could not be trusted in establishing the diagnosis of hypertension. If we use these two pressures we will find three groups: (1) A big group in which both the systolic and diastolic are elevated; (2) Cases in which the systolic is above normal and the diastolic is normal, and (3) A group in which the systolic is normal and the diastolic above normal. There are cases of hypertension with a normal diastolic pressure. The prognostic significance of the diastolic pressure must be determined from the experience of insurance companies. It will be a number of years before we have this information. Strange to say, there are not many statistical studies of very significant figures on the prognostic significance of high systolic pressure. Fischer found no increased mortality in accepted risks with systolic pressures of 140 to 750 mm. Hg.; but the death rate is much above the expected mortality with pressures above 150 mm. Hg. I have always considered a systolic pressure above 150, on repeated examinations, as hypertension.

Dr. Wetherby reported recently that in Dispensary patients over half above 50 years of age had a systolic pressure above 150 mm. Hg. Dr. Major found about the same proportion in the Ancker Hospital and Dispensary. Major found a systolic pressure above 150 mm. Hg. in about 40 per cent of the visitors above 50 years of age at the Ancker Hospital.

We are no longer sure what constitutes hypertension in the older age groups. Life insurance statistics deal largely with selected groups under 50 years of age. One of the first things we must find out is the normal pressure of the older groups. We have gone on the supposition that anything above 150 is hypertension. In about 12,000 postmortems which we have performed, 15 per cent of those over 50 years of age died from hypertension.

We have little or no knowledge as to the cause of primary hypertension. We have a lot of cases called secondary hypertension, practically all of which are secondary to kidney disease. That is the reason why Theodor Fahr is so strong on the kidney as the basis of hypertension. A fulminating primary hypertension is probably renal in origin; but in the great majority of hypertension cases there is not preliminary kidney disease but some unknown disturbance which keeps up a constant spasm of the arterioles of the body. Some 80 per cent of the arteriolar system is not involved. In the early cases of hypertension you can relax that spasm with nitrites. There is much evidence that the main thing is spasm, but what is the cause of that spasm? The only known factor in primary hypertension is inheritance. If it is inherited there must be some sort of physiological basis for it. Ninety per cent of the cases of hypertension appear after the age of 40 years. Hypertension is rare in young people.

Dr. J. F. Fulton (St. Paul): Fundus changes constitute a very important factor in the clinical findings of hypertension so satisfactorily described by Dr. McCloud in his very valuable paper this evening. Asthenopia associated with come-and-go vision, together with highly congested disc and retina, is frequently an early symptom. High blood pressure and retinal arteriosclerosis frequently exist independently of each other. There are those who claim that fundus changes are met with in less than 50 per cent of the cases of hypertension; on the other hand, there are others who maintain that circulatory retinal changes are always found in persistent high hypertension if they are carefully investigated, commencing with spasm of the smaller vessels, resulting in narrowing of the arteries, kinking of the veins, engorgement and tortuosity, commencing twisting of the smaller arteries either between disc and maculæ or more frequently in the periphery, associated with the formation of small white spots in the retinal structure increasing in number as the condition lasts. Retinal hemorrhages demand careful study. The large flame-shaped hemorrhages taking place in the fibrous layers of the retina associated with edema are indicative of serious kidney pathology, while the small round punctate hemorrhages situated in the deeper retinal structures are met with and without hypertension. There is no relationship, however, between the height of blood pressure and the degree of arteriosclerosis. The white streak frequently seen along the course of the vessel is indicative of lymphatic complications.

I wish to call attention to the recently constructed self-illuminated ophthalmoscope as being of great value in detecting early changes in the arterioles in the retina.

Dr. R. T. LaVake (Minneapolis): I would like to ask Dr. Bell about the early cases, those in young people. What does he mean when he says that he doesn't believe there is very much hypertension in the very young? How young? I have had several cases sent to me by men thinking that the patient had a toxemia of pregnancy, and I thought so too until I had followed them carefully for a considerable time. One was a girl of 20. She had a blood pressure of 160. On her father's side they all had hypertension. She never showed any kidney trouble so far as I could find, and she showed no nitrogen retention. She went all through pregnancy without any change in blood pressure.

Dr. Bell: I had reference particularly to the college age. Hypertension is rare in college students. We had one case that began at 5 years of age; but I do not believe that it often begins in early life.

Dr. LaVake: Another interesting feature was that this patient moved away and came back ten years later, and went through another pregnancy. The pressure had not varied in ten years.

Dr. McCloud (in closing): I would like to rise to the defense of the insurance statistics and our "be-

loved" examiners. In the 707,000 cases that were studied, those cases were not examined by "ordinary practitioners," but by experienced men, many of whom were medical referees and medical directors who spend nearly all of their time doing nothing but that sort of thing. However, that number constituted just a small portion of the number of cases examined; these were merely selected cases by that group of examiners. There were only 7,000 in that group that were ratable cases.

I wish to thank the members very much for their discussion of this paper.

The meeting adjourned.

R. T. LaVake, M.D.,
Secretary.

PROGRESS

Abstracts to be submitted to Section Supervisors.

Members are urged to abstract valuable articles which they run across in their reading and send the abstracts to the physicians in charge of the respective sections. In order to avoid duplication it would be well to communicate with one of the section supervisors before the article is abstracted.

LA SALLE BLDG., MINNEAPOLIS

THE PHYSIOLOGICAL MECHANISM OF PNEUMOTHORAX: F. Dumarest (Revue de La Tuberculose, 1929, X177). According to Forlanini the primary cause of the progressive nature of ulcerative pulmonary tuberculosis is the respiratory traumatism which is exerted upon a tissue that has lost its capacity to expand. Dumarest's former assistant, Parodi, has recently published a book on Pneumothorax which is concerned with the relations of the respiratory mechanism to the technic of the procedure.

As regards normal physiology, Parodi considers the movements of the thorax dependent on the elasticity of the lung: first, the structural elasticity of retraction, due to elastic fibres in the lung, which is effective during expiration; and, secondly, the functional elasticity which distends the lung during inspiration, brought about by the enlargement of the thorax and which represents the capacity of the lung for change in form.

It is easier to immobilize the apex of the lung than the base, and infiltrated rather than healthy areas because their capacity for retraction is increased while their power of distention is lessened. The various parts of the lung are independent of each other and this makes selective collapse possible. It is difficult to collapse healthy lung tissue. In such tissue there may even be reversed pressure due to interference with expiration by closed bronchioles and by muscular bands. In order that healthy lung tissue be collapsed, the air in the alveoli must be absorbed or expelled. Gradual relaxation of the muscle fibres increases the degree of possible collapse.

In the child, collapse can be brought about more easily as the elasticity of retraction is much greater than that of distention.

The diaphragm is an index of the elasticity of the lung structure. When there is infiltration, the diaphragm ascends; when the elasticity of the lung is diminished, as in emphysema, the diaphragm descends.

The rôle of the mediastinum is no less important. In the dog the mediastinum is very movable and a complete collapse of the lung cannot be secured without causing serious cardiac and vascular difficulties.

In the tuberculous patient the mediastinum is usually more fixed than in a healthy person, and an immediate complete collapse becomes possible. The degree of mediastinal fixation is therefore always important, but less so in bilateral pneumothorax.

When a pneumothorax is started, the amount and the rapidity of penetration of the gas under atmospheric pressure gives valuable information as to the state of retraction and the capacity for distention of the lung.

The rapidity with which the gas is taken and the amount of collapse secured are dependent upon the degree and nature of the lesions and of the lung tissue, whether more or less emphysematous. Neutralization of the tendency to expand is dependent on the state of the muscles and the power to inspire.

To produce a selective collapse it is necessary to introduce only that amount of gas which will neutralize the structural elasticity in the diseased area without seeking to reduce the functional elasticity of expansion in the healthy part of the lung. This can be brought about only when negative pressure is used in giving the pneumothorax.

Parodi has devised an apparatus called an "ergomanometer" which permits a closer analysis of the factors concerned in collapse than does the ordinary manometer.

A. T. Laird, M.D.

INDICATIONS FOR THORACOPLASTY: Karl Fischell (Amer. Rev. of Tuber., 1928, XVIII, 552/4). The more extensive the lesion on the compressed side, the smaller is the amount of normal lung tissue that will be affected by the operation and the better will the functional deficit be compensated by the increased activity of the better side.

Acute cases with short duration are not suitable for rib resection before a tendency to retraction is demonstrated. Operation is contraindicated in the stage of defense and should be attempted when the stage of re-

pair is reached when the heart and lung have had time to adapt themselves to diminution of the breathing space and are ready for increased compensatory function and, above all, retraction in different parts of the chest, thickening of the pleura, displacement and fixation of the thoracic viscera have developed, which indicate the necessary tendency to fibrosis which can be intensified by thoracoplasty.

Thoracoplasty acts on the chest wall, phrenicotomy immobilizes the floor. We know of no means to make the mediastinum resistant unless it is fixed by adhesions. If it is not fixed, paradoxical breathing or mediastinal flutter occurs.

Fever, cough, dyspnea and rapid pulse and palpitation are usually observed during the first week, the combined effect of shock, pulmonary and cardiac embarrassment and increased absorption of toxins.

The cardio-pulmonary reaction will be milder if the compression is done in two or three stages.

Other contributory factors to the postoperative reaction are sputum retention, aspiration pneumonia, and toxic crises. The latter resembles a true tuberculin reaction and will be mild or absent in chronic cases.

The risks of operation are greater if performed at too early a period. The case must be mature, as a cataract must be before it is removed.

In exudative lesions compression is not advisable or possible.

Marked constitutional symptoms such as high fever, dyspnea, cyanosis, and rapid pulse represent a formal contraindication.

The general condition of the patient must be taken into account. He must have a well functioning heart, and meet the requirements of a good surgical risk as to blood pressure, hemoglobin, red and white count and coagulation time. Contraindications on account of the better side must be stricter than in pneumothorax. It is wise to test the adaptability of the other side by phrenicotomy first.

Classical contraindications are extensive tuberculosis in other organs, extreme youth or age and cardiac and renal disease and diabetes. The author considers involvement of the larynx or of the intestines a contraindication. Myocarditis and valvular lesion of the heart and contraindications.

A. T. Laird, M.D.

INFRACLAVICULAR FOCI OF INFILTRATION AS EVIDENCE OF INCIPIENT TUBERCULOSIS OF THE LUNGS IN YOUNG ADULTS: Prof. Dr. H. Assmann (Radiology, XIV, Feb. 1930, 93). The author describes an isolated, rounded focus of varying density, usually situated just below the clavicle, in the lateral part of the pulmonic field which he considers to be a characteristic type of pulmonary lesion in the early stage of tuberculosis, particularly in young adults. He first described this lesion in 1922 and again in 1924. The apices are uninvolved in this type of tuberculosis. The position of this focus at a distance below the surface presents few or no physical signs, and the general clinical signs are also often minimal.

The anatomic basis is assumed to be the beginning tuberculous pneumonic infiltration, *i.e.*, an exudative process which often leads to caseation and central necrosis and thus to cavity formation which is well demonstrated on the *x*-ray plate. The author does not consider this a primary focus of infection since that usually occurs in childhood and is generally overcome, but rather a re-infection in an aërogenic manner.

The prognosis is generally favorable under proper treatment and the shadow of the focus may disappear, leaving only a very small linear scar.

MAYO CLINIC, ROCHESTER

RADIOLOGY OF THE THORAX: Samuel Brown, M.D. (Rad., Dec., 1929, XIII, 515). The author feels that antero-posterior and lateral views of the chest are superior to stereoscopic plates except in early tuberculosis. There is a constant relationship between the size of the heart and the thorax and this is expressed in a formula developed by the author. The *x*-ray anatomy of the thorax is well described. A knowledge of the exact position and relationship of the intrathoracic structures in the antero-posterior and lateral views is of great value in recognizing abnormal changes affecting any of the structures. The points discussed are well illustrated by twenty-four plates taken in the antero-posterior and lateral views.

Jacob Sagel, M.D.

THE ROENTGENOLOGIC MANIFESTATIONS OF INTRACRANIAL DISEASE: John D. Camp, M.D. (Rad., Dec., 1929, XIII, 484). In this type of work, stereoscopic plates in the lateral view, antero-posterior, and postero-anterior plates should be taken. Frequently, additional views of special structures are necessary. In order of their importance the various roentgenologic signs of intracranial diseases may be grouped as follows: (1) calcification within the lesion itself, (2) localized changes in the bone such as destruction, proliferation, or both, (3) changes in the sella turcica, (4) changes in the bone resulting from increased intracranial pressure, (5) displacement of the pineal shadow, (6) air in or about the lesion, (7) increased vascularity of bone.

Calcification within the lesion occurs in only a small percentage of cases. The usual change in the

bones overlying a contiguous tumor is a localized thinning due to pressure. The lesions producing deformities of the sella turcica are: (1) intrasellar tumors involving the pituitary gland, (2) suprasellar lesions, (3) disease of the sphenoid bone. Displacement of the shadow of the pineal gland is a very important sign in diagnosis. Increased vascularity of bone must be interpreted cautiously due to marked variations in the prominence of the diploë and other vascular markings. This sign by itself is not worth much. The article is well illustrated and a large bibliography is appended

MANKATO CLINIC, MANKATO

EARLY RHEUMATIC INFECTIONS IN CHILDHOOD: C. C. McLean, M.D., Birmingham, Ala. (Arch. of Ped., November, Vol. XLVI, No. 11). Early rheumatic infection of childhood is characterized by an insidious onset. Many children complain of slight pains in the legs, feet or joints. They begin to drop objects and have difficulty in writing. Examination will show an anemic child who is nervous, excitable, high strung and underweight. Often no murmur is heard, but the heart action is rapid, with the apex impulse exaggerated.

When a diagnosis of rheumatic infection is made it is not always given the importance that it deserves. Feer states that 80 or 90 per cent of all cases of rheumatic infection will have a certain degree of heart involvement.

The most common symptoms are: (1) Poor appetite and failure to gain weight; (2) nervousness, irritability and fatigue; (3) repeated attacks of tonsillitis and nasopharyngeal infection with temperature; (4) pain in legs, joints, or stiffness of limbs. Seventy-one per cent have soft blowing systolic murmurs, the second heart sound being accentuated in each case. There were 103, or 87.3 per cent, underweight for their height.

Every child with manifestations of an early rheumatic infection should be given the benefit of the doubt and managed accordingly. The foci of infection should be found and removed when possible. Rest in bed and forced feeding is very important in this type of case. They are given a six-meal diet, with special emphasis on liver, spinach, prunes, whole wheat breads and cereals. They are also given iron and cod liver oil.

Every child with manifestations of an early rheumatic infection is a potential cardiac patient, and should be managed accordingly.

R. N. Andrews, M.D.

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

BOOKS RECEIVED FOR REVIEW

General Medicine. Edited by George H. Weaver, M.D., et al. 829 pages. Illus. Cloth, $3.00. Chicago: The Year Book Publishers, 1929.

Comment Rajeunir. Dr. H. Jaworski. Albin Michel, Editor. 250 pages. Paper, 12 francs. Paris: Albin Michel, 22, Rue Huyghens, 1930.

Getting Well and Staying Well. Dr. John Potts. 221 pages. Cloth, $2.00. St. Louis: The C. V. Mosby Company.

Symptoms of Visceral Disease. Dr. Francis Marion Pottenger. 426 pages. Illus. Cloth, $7.50. St. Louis: The C. V. Mosby Company.

OUTLINE OF PREVENTIVE MEDICINE. Prepared under the auspices of the Committee on Public Health Relations, New York Academy of Medicine. Editorial committee: Frederic E. Sondern, Charles Gordon Heyd and E. H. L. Corwin. 398 pages. Price, $5.00. New York: Paul B. Hoeber, 1929.

This is an interesting and instructive book. Preventive medicine is a field that each practitioner should know and practice, and this book covers every field of medicine. There are twenty-one chapters, each chapter by a different author. The ground is well covered in a brief and interesting way and offers to the specialist an opportunity of covering the newest in other fields in a short period of time. It is a book worth reading.

A. N. Bessesen, Jr., M.D.

TULAREMIA. Walter M. Simpson, M.S., M.D., F.A.C.P. 162 pages. Illus. Cloth, $5.00. New York: Paul B. Hoeber, 1929.

This book is an extremely interesting presentation of a disease discovered and developed entirely by our own men. The printing is large and easy to read, 136 pages. It is fully illustrated and a large bibliography gives credit to each worker in the field. This book is not only interesting but instructive, and should be read by every American physician because of its inspiration. It promises a delightful evening at home and one the wife will enjoy as well, for it reads like a novel.

Alfred N. Bessesen, Jr., M.D.

THE TREATMENT OF FRACTURES. Lorenz Böhler, Vienna. 185 pages, 234 illustrations. Cloth, $5.00. Authorized English translation by M. E. Steinberg.

Dr. Böhler has written an excellent book, covering the entire field of fractures. After carefully reading this book, it is the opinion of the reader that Dr. Böhler has given us many new ideas, which may somewhat revolutionize our treatment of fractures. It is a pronounced departure from the usual orthodox fracture treatment. While the author stresses non-operative treatment, his methods really are more radical than our present operative treatment. Dr. Bohler has had the fortunate experience of treating many hundreds of fractures in Austria, under conditions which are not available in this country. Undoubtedly his methods are excellent in the hands of well trained men, with good hospital facilities, and a surgical team of six or eight people to carry out his method of treatment.

He emphasizes the use of local anesthesia, and interfragmental anesthesia almost universally. He favors the non-padded cast, recommends large amount of equipment, and goes into minute detail as to all the requisites necessary for treatment. He emphasizes immediate, forcible reduction, and uses skeletal traction in most all of his fractures. He introduces several new splints, both for bed treatment and ambulatory treatment. He has outlined his principles very clearly, but many of his methods are peculiar to his clinic alone. He has emphasized function very thoroughly, and this alone is a great contribution. Some of his operative methods, especially those for the treatment of pseudoarthrosis, are obsolete.

I believe this book is a definite contribution to the treatment of fractures, and I would recommend it to all men who have had training and experience in fracture work, but it is certainly a book to be kept out of the hands of people who rarely treat fractures, and who might become enthusiastic about these methods.

E. A. Regnier, M.D.

PHYSICIAN WANTED—Young physician to do general practice and resident work in clinic operating sixty-bed hospital in South Dakota. Excellent opportunity for clinical experience and good permanent clinic affiliation. Moderate salary offered for first year with opportunity for permanent connection following. Address D-58, care Minnesota Medicine.

LABORATORY TECHNICIAN WANTED — Well trained girl capable of performing the Kahn test, basal metabolism, blood chemistry, and preferably, but not necessarily, *x*-ray work. Excellent future in South Dakota Clinic. Address D-56, care Minnesota Medicine.

INTERNIST WANTED—Opening for well trained man in South Dakota clinic. Exceptional opportunity for future available to right man. Address D-57 care Minnesota Medicine.

WANTED—Salaried appointments for Class A Physicians in all branches of the medical profession. Let us put you in touch with the best man for your opening. Our nation-wide connections enable us to give superior service. Aznoe's National Physicians' Exchange, 30 North Michigan Ave., Chicago. Established 1896. Member The Chicago Association of Commerce.

RELATIONSHIP BETWEEN CHILDHOOD AND ADULT TYPES OF TUBERCULOSIS

J. A. Myers, Ph.D., M.D.

Chief of Chest Clinic, University of Minnesota, and Medical Director, Lymanhurst School for Tuberculous Children

Minneapolis

THE army of the tuberculous is recruited from those infected in childhood." This statement has been interpreted in several ways. Some believe that the initial infection is always contracted in childhood, lies dormant for a time, then overwhelms its host. They believe that after the first infection exogenous sources of tubercle bacilli play no part. The most modern interpretation is that tuberculous infection, whether it first occurs in infancy, childhood or adult life, prepares the way for the adult type of tuberculous disease. The first infection confers some immunity which results in an ability of the tissues to fix or hold bacilli subsequently gaining entrance to the body wherever they find lodgment. Thus instead of being swept off to the regional lymph nodes they remain for the most part in their place of lodgment where they multiply and produce disease. This brings us to the points of differentiation between the childhood and adult types of tuberculosis.

1. The childhood type often develops in children, but may also occur at any time in life in a person who has not previously been infected with tubercle bacilli. Therefore, the childhood type is a result of first infection. The adult type is usually seen in adults, but may appear in children. It is the result of reinfection.

2. The childhood type may be found in any part of the lung, whereas the adult type usually makes its first appearance in the region of the apex, most often just beneath the clavicle.

3. In the childhood type the hilum and tracheobronchial lymph nodes are very quickly involved, whereas in the adult type these nodes usually do not become involved.

4. In the childhood type both in the lung parenchyma and in the regional lymph nodes the lesions usually become caseous and later calcified. Cavitation is rare and there is only slight tendency towards fibrosis. Around the parenchymal lesion still later true bone may be deposited. In the adult type there is a strong tendency for the caseous lesions to become excavated and for fibrous tissue to appear.

But what is the relationship between the childhood and adult types of tuberculosis? Was Ranke correct when he likened tuberculosis to syphilis by speaking of primary, secondary and tertiary stages? He described the primary lesion as one resulting from first infection, and located in any part of the lung parenchyma; the secondary lesion as one developing from the primary, but located in the hilum lymph nodes, and the tertiary as one developing from the secondary but located in the lung parenchyma. Evidence has accrued to cast some doubt upon the correctness of Ranke's assumption. When tubercle bacilli first infect the lung (at any age of life) there is no immunity present and consequently the lung tissue does not have the ability to fix or hold tubercle bacilli in their place of lodgment. Therefore, many are carried to the regional lymph nodes, where they set up disease almost simultaneously with that in the lung parenchyma. The lesions resulting in the lung and hilum nodes from this first infection we now speak of as the childhood type of tuberculosis. The adult type may appear soon or years after the primary type

or it may never appear. When it does, however, its usual location is in the lung parenchyma at the level of or above a plane passed horizontally through the chest slightly below the clavicle. The remoteness of these lesions from those of the tion. Again, the initial lesion that established the partial immunity may have been elsewhere than in a lung. If this group could be added to those with demonstrable childhood tuberculosis a very high percentage of those with clinical adult type

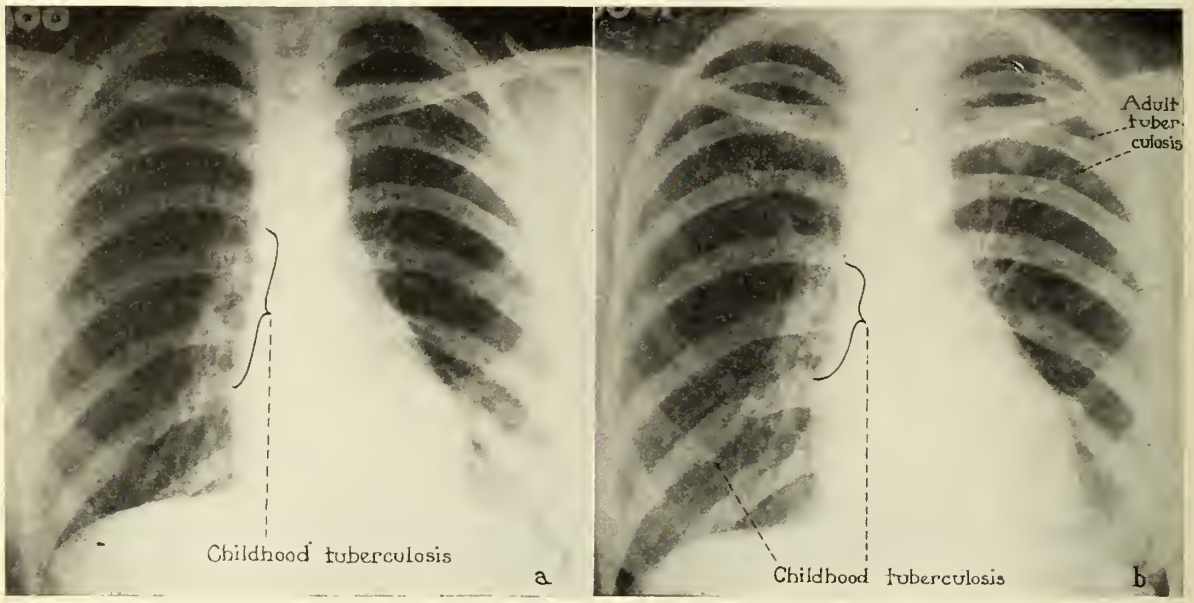

Fig. 1A. E. O., aged 17. Roentgenogram of the chest taken on April 14, 1927. Childhood tuberculosis right hilum. Cutaneous tuberculin test strongly positive. Exposed to sister who suffered from pulmonary tuberculosis and died in March, 1927.
Fig. 1B. E. O. Roentgenogram taken on December 29, 1927, of the same chest as seen in Fig. 1A. In addition to childhood tuberculosis in the region of the right hilum there is now adult tuberculosis in the apex of the left lung.

childhood type often being in the opposite lung again casts some doubt upon Ranke's assumption. The remoteness, together with the fact that in many cases that develop the adult type the exposure to tubercle bacilli through intimate contact has been continued or resumed, leads one to believe that a good percentage of cases of adult type tuberculosis are due to reinfection from exogenous sources.

In a recent study we found approximately 50 per cent of teen age girls and boys suffering from clinical adult type of tuberculosis also had definite evidence of the childhood type having existed as manifested by calcifications. The findings of Rathbun, McCain and McPhedran have been similar to ours. Therefore, it is obvious that the childhood type of tuberculosis easily demonstrated in the living precedes the adult type in approximately 50 per cent of cases. Obviously the childhood type can not always be demonstrated in the living as the calcifications may be obscured by the diaphragm, heart and other dense structures such as those composing the bony framework. Again, the lesions may be so small as to escape detection except on postmortem examination. Again, the initial lesion that established the partial immunity may have been elsewhere than in a lung. If this group could be added to those with demonstrable childhood tuberculosis a very high percentage of those with clinical adult type of disease would have been recruited from those ranks—perhaps a good many more than our

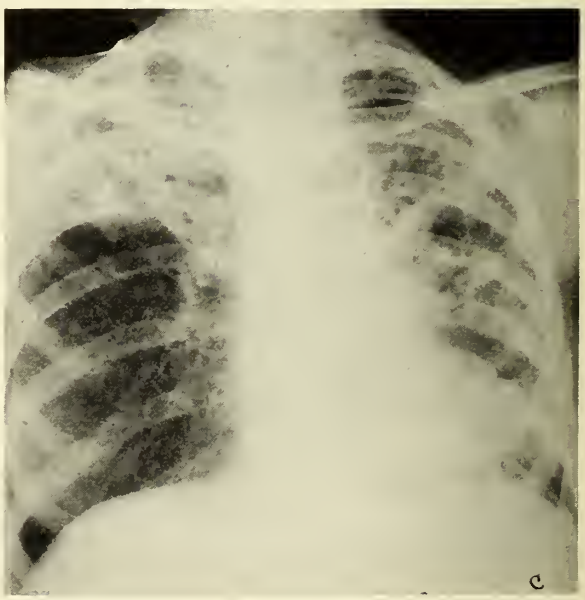

Fig. 1C. E. O. Roentgenogram taken on July 8, 1929, at the Glen Lake Sanatorium of the same chest as seen in Figs. 1A and 1B. In addition to the childhood tuberculosis in the region of the right hilum the entire left lung and the right lung to the level of the third rib are involved with adult type of tuberculosis. This patient died on August 15, 1929.

proved 50 per cent and Rathbun's estimated 75 per cent.

A second way of obtaining evidence is by watching children with the childhood type of disease over a period and actually observing the development of the adult type of disease (Figs. 1 and 2).

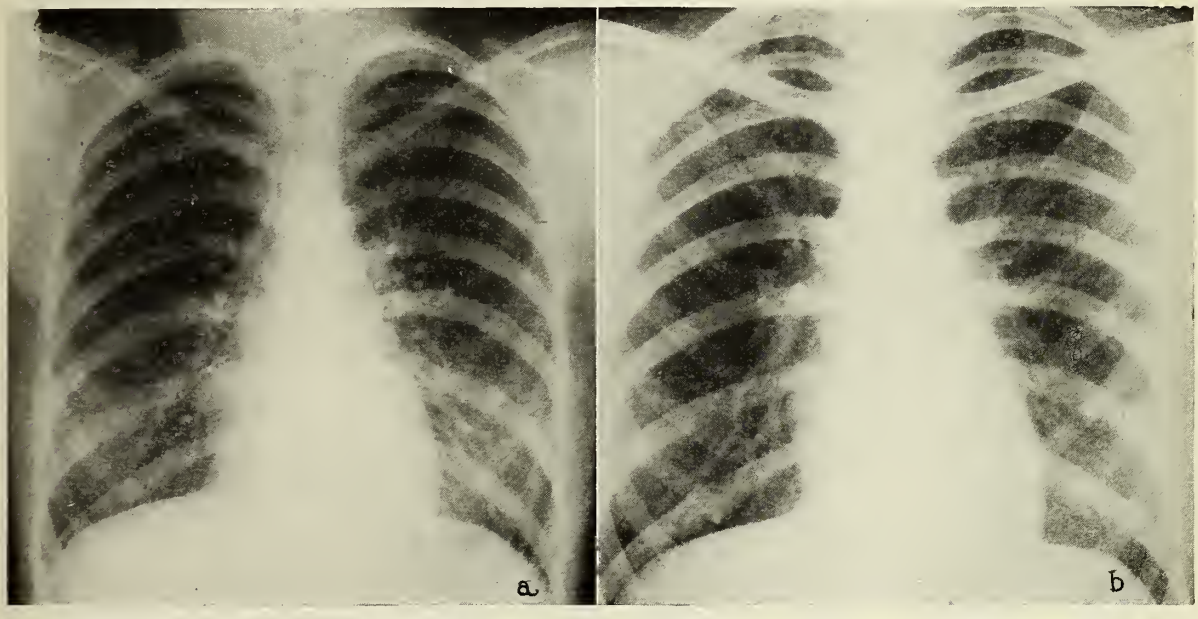

Fig. 2A. P. H., 14 years of age. Roentgenogram of the chest taken on February 16, 1926. Childhood tuberculosis right hilum. Father suffering from tuberculosis with a history of cough and expectoration since 1920. One sister died a year before this roentgenogram was made. Cutaneous tuberculin test strongly positive.

Fig. 2B. P. H. Roentgenogram of the same chest as seen in Fig. 2A, but taken on June 5, 1929. Childhood Type of tuberculosis right hilum, adult type with cavitation right upper lobe. Exposure to father has continued since roentgenogram illustrated in Fig. 2A was made.

The number of children at any age with the childhood type of tuberculosis is relatively small, but they contribute in a large way to the group in later life with the adult and killing type of tuberculosis. Therefore, such a definite relationship exists between these two types of tuberculosis that one of our great problems is to seek out the infants, children and young adults who have developed the childhood type and put forth every effort to help them avoid the development of the adult and fatal type of disease. Definite procedures to accomplish this have been tried and found effective.

That tuberculosis is a communicable disease is a well established fact. Galen once stated: "It is dangerous to live with consumptives and with those whose foul breath imparts a heavy odor to the rooms in which they lie." From the middle to the last of the eighteenth century, drastic isolation laws were enacted and enforced in Spain and Italy, so drastic, in fact, that great hardship was imposed upon not only the patients but also the physicians who neglected to report cases to the health authorities. These laws were based almost entirely upon personal opinion, for there was at that time no scientific proof that tuberculosis was contagious. One Italian physician said: "Pulmonary consumption is of such a malignant nature in our country that even after the death of the sick person there remains after him the seed of his malady hidden and unseen in many houses with serious danger to those who move into them thoughtlessly, and indeed some of this seed is so penetrating that it can be communicated even without immediate contact with the infected person or thing." One school was convinced of its contagious nature while another clung to the view that it is inherited. Since the foundation was purely a matter of personal opinion, the laws and their makers were severely criticized. As a result, many people joined the school believing in the hereditary nature of tuberculosis. Although it has been proved over and over that this school is wrong, the public today is still suffering from the influence of its teachings.

Klenke, Villemin, Cohnheim, Koch and many others have proved beyond doubt that tuberculosis is a contagious disease. The literature abounds with clinical observations and references to its contagiousness, particularly in infancy and childhood. The Brontë family, made famous by

the writings of Emily and Charlotte, was almost annihilated by this disease. All of the five children, but one, died from tuberculosis before the age of forty years. Any physician, even today, who has made a study of tuberculosis as it exists, has seen families with similar experience. Dr. L. M. Roberts of Little Falls, Minnesota, has cited the following: "The parents came from

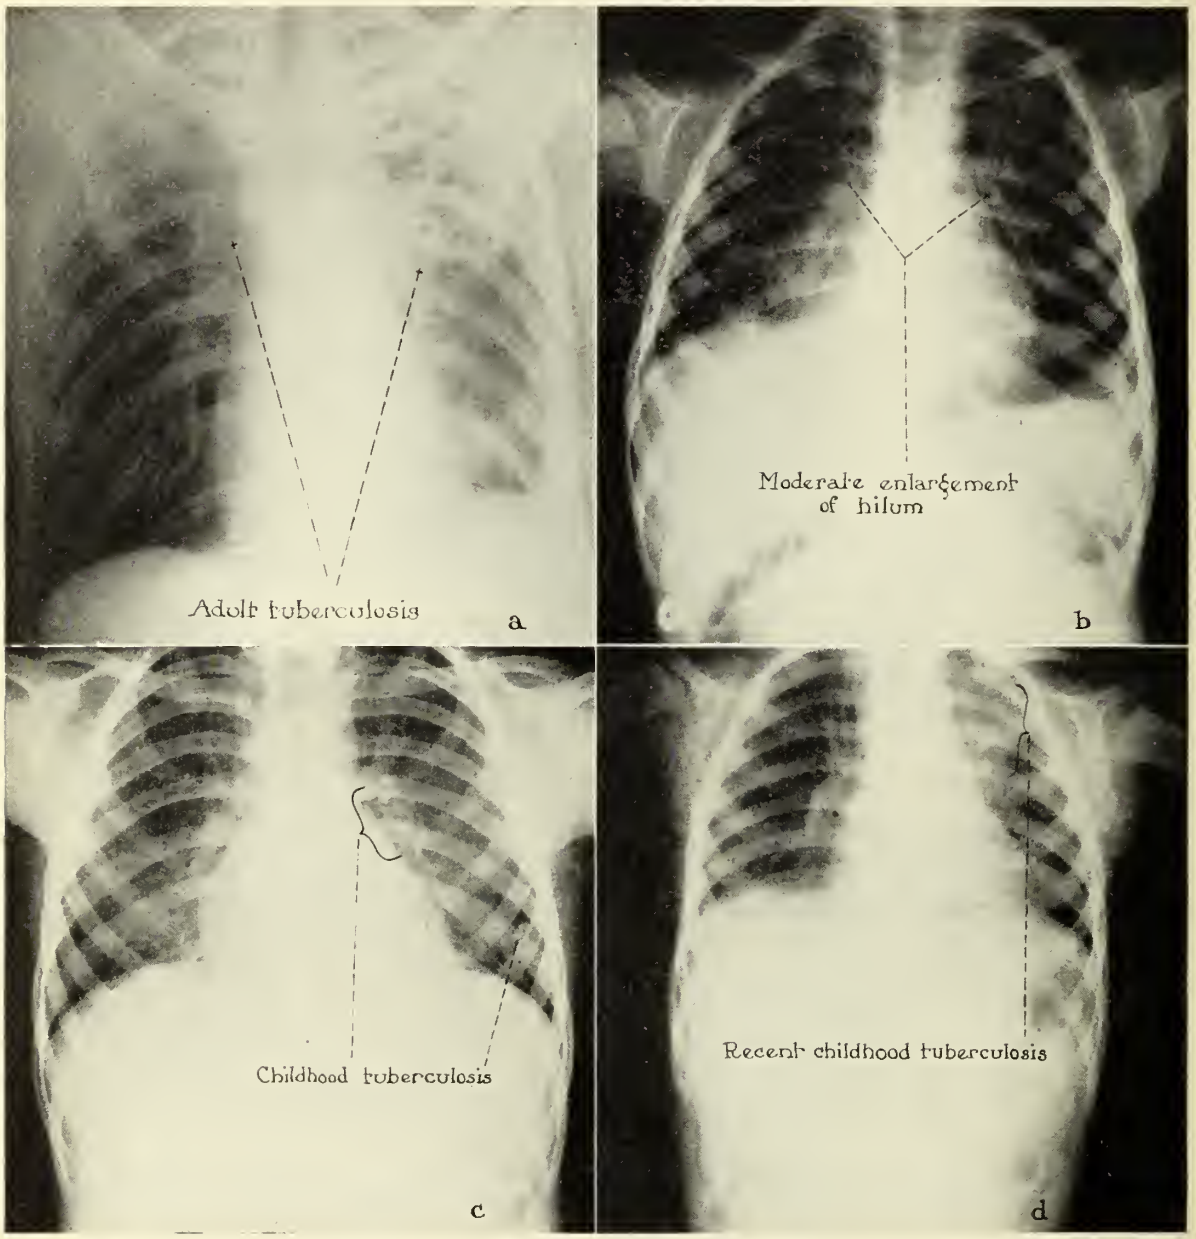

Fig. 3. Roentgenograms of four members of the same family. On April 10, 1929, the father was seen in his home. He had the appearance of one with advanced tuberculosis. It was learned that his disease was detected two years before, but in order to avoid the Health Department he moved to another city. There were three children in the home. The chest conditions of the father and the three children are seen in the illustrations as follows:

A: G. C. Father, aged 35. Roentgenogram taken in April, 1929. Advanced bilateral pulmonary tuberculosis, adult type. Recent hemorrhage. Quite ill.

B: D. C. Son. Two years of age. Roentgenogram taken on April 18, 1929. Moderate enlargement of the hilum on each side. The findings in the lungs are those usually seen in acute nontuberculous respiratory infection. Cutaneous tuberculin test strongly positive. At the time the roentgenogram was made this child had a temperature of 102°. A few days later he died of tuberculous meningitis.

C: G. C. Son. Three years of age. Roentgenogram taken on April 18, 1929. Childhood type of tuberculosis represented by primary focus in left base and calcification in left hilum. Cutaneous tuberculin test strongly positive. Apparently in good health.

D: B. C. Daughter. Age approximately one year. Roentgenogram taken on April 18, 1929. Childhood tuberculosis in the inflammatory stage, left upper lobe. Tuberculin test strongly positive. Child's general health is reasonably good.

the old country, where I am sure the mother contracted tuberculosis of the lungs. She gave birth to nine children, quite close together; one by one they died of tuberculosis, mostly very young. Only one or two passed their teens, the last to go was about twenty-six—then the father died, later the mother herslf." Lampson, Slater and Richdorf and Hetzler have called attention to the spread of tuberculous infection from one member of a family to others. In some instances as many as 100 per cent of the members of families have become infected. Over and over again, Krause has called attention to the great dangers of exposure to tuberculosis. In a scholarly work on the contagiousness of tuberculosis, Opie and McPhedran both descriptively and graphically have shown that not only tuberculous infection but also tuberculous disease is communicable.

The following cases show how tuberculous infection and disease resulting from exposure to any tuberculous member of the family may cause illness and death among other members of the family.

One case is that of a man of thirty-one years, who first reported for an examination in January, 1924. Recently his infant died from meningitis, which the physician found was tuberculous. The father was sure that his trouble was only bronchitis, although the history indicated that he had not been well for at least a year. The examination revealed advanced tuberculosis with tubercle bacilli in the sputum. After all the evidence was in, he was easily convinced of the truth and immediately gave up his work and in five weeks he was admitted to a sanatorium. He was extremely homesick, and decided to return to his home to continue treatment. Before his return home, a third child was born. A few weeks later this infant died of tuberculous meningitis. Not long after, the father died of the same disease. We have recently seen the wife and the oldest and only remaining child in the family, and although neither have any evidence of clinical tuberculosis, both react positively to tuberculin.

When tuberculosis has been detected in a family it is of great importance that good coöperation of the patient and the family be secured. In some places laws exist which, when enforced, compel the isolation of the patient. If the physician will devote time and thought to his cases and manifest much interest in them, he will in the majority of instances be able to inspire enough confidence so that all concerned are willing to coöperate with him. In the occasional family, however, it is difficult to obtain proper coöperation. Recently a mother brought three children for examination, each of whom had a marked reaction to tuberculin. A brief conversation with the mother convinced her that in all probability there is a case of tuberculosis among the children's associates. She consented to be examined and to have her husband examined, but in neither case could we find any evidence of pulmonary tuberculosis. Inquiry about other associates revealed the fact that a grandmother at one time had lymph nodes removed from her neck, and that she has coughed for years, but all attempts have failed to result in the slightest degree of coöperation from the grandmother.

A member of an orchestra had a profuse pulmonary hemorrhage while performing. When we saw him, he had extensive tuberculosis involving the greater part of the left and the upper lobe of the right lung. He stated that he had never been ill, but upon investigation we learned that two years before his case had been diagnosed in one of the free clinics in the city of Minneapolis and reported to the Health Department. The family disappeared, leaving no address, and their whereabouts was unknown to the Health authorities until the hemorrhage occurred. The examination revealed advanced tuberculosis (Fig. 3A). His mother, wife and three children were in the home, one of whom approximately two years old (Fig. 3B) had been rather drowsy for a day or so. The history of exposure and the symptoms led us to suspect tuberculous meningitis immediately. The child was sent to a hospital, where the findings were typical of tuberculous meningitis, and death resulted a few days later.

Another child of approximately three years was found to have a marked tuberculin reaction, and the examination revealed childhood tuberculosis with a primary focus in the lung parenchyma and calcification in the lung hilum on the same side (Fig. 3C). A third child of approximately one year had what appeared to be childhood tuberculosis in an active stage involving the upper lobe of the left lung (Fig. 3D). There was definite enlargement of the hilum. The mother showed a high degree of allergy, but no evidence of clinical tuberculosis. The grandmother was very thin and coughed, but refused examination. The father, who was without funds, was advised to enter an institution immediately, not only for his own sake, but for the sake of his associates, particularly his own family. He refused on the ground that he did not feel ill enough for any such treatment. We were finally able to convince him that the infant should be sent to a sanatorium. This was done, but after a few weeks in the institution the child developed pertussis. This appeared to be a rather serious complication with a recent parenchymal lesion, and after the pertussis had subsided, the *x*-ray showed extension of the disease to the entire left lung with pleural effusion on that side. The child looked ill, but recent films show considerable resolution of the parenchymal disease, and the infant's general condition is much improved. We feel that the prognosis in this case would be definitely improved if the exogenous infection could be stopped.

In March, 1924, a man of twenty-one years reported

for an examination of the chest, giving a history of having lost a sister from tuberculosis one year before. The source of her infection has not been determined. This young man was found to have moderately advanced tuberculosis and was sent to a sanatorium. He remained there for nine months and showed evidence of marked improvement, but at present his condition is critical. In December, 1925, a sister of eighteen years was brought home from college acutely ill. She had an extensive pulmonary tuberculosis, but later responded well to artificial pneumothorax. She is now working. In February, 1929, a brother of thirty-two years was examined, and found to have hopelessly advanced tuberculosis. He died in less than a year from the time his disease was detected. Of the entire family there is one sister who has remained free from tuberculosis. The source of the original infection in this family has not been determined. However, there are reasons to suspect that the father may be a chronic case of tuberculosis, although he has not submitted to examination. This and the previous cases show that sufficient cooperation to prevent the spread of infection and disease in families is often difficult to secure.

Almost every physician engaged in clinical tuberculosis work has seen a number of cases of *conjugal tuberculosis*. Galen said: "Besides there is a danger in being extremely intimate, especially in the conjugal relationship, with those who suffer from consumption." Villemin once remarked: "In the course of my practice, I have more than once been astonished to see wives begin to present the first symptoms of pulmonary phthisis in a short time after their husbands, with whom they had shared the bed up to the last moment, had succumbed to this disease."

Some authors have been inclined to believe that conjugal tuberculosis does not occur very frequently, but more recent accurate aids in diagnosis have shown that it is by no means uncommon. Arnould collected statistics on 53,069 families in each of which the wife or husband suffered from tuberculosis. In 8.43 per cent he found that both wife and husband were tuberculous. Opie and McPhedran made a study of this subject and found that in twenty-one families where tuberculosis existed in the husband or wife it also was present in the consort of ten families.

Tuberculosis may be considered in a large part as a *family disease*. Therefore, whenever a case is detected, all members of the family should be examined. When this procedure is generally practised, many cases of tuberculosis will be detected among children and adults earlier in the course of the disease than has been true in the past. Unfortunately tuberculosis may spread outside the family. In other words, so far as we know, there is no inheritance which makes only the members of the family susceptible. Other close associates are perhaps just as liable to become infected. It is also true that a person from outside the family may bring tuberculosis into the home. Over and over again we see tuberculosis developing in families who have always been free from it, and later trace the disease to a domestic who has been brought into the home. The frequent occurrence of such cases should convince us that every person being brought into our homes to live over a considerable period of time should be most carefully examined: first for tuberculous infection and second for tuberculous disease. Because of the greater prevalence of tuberculosis among Negroes and American Indians than among the white races one should be doubly sure that careful examination is made of members of these races before they are employed in homes.

Every case should be reported to the Health Department. It is a lamentable fact that the medical profession has not taken more pride in reporting tuberculous cases to health departments as required by law. The number first reported at the time of death is almost unbelievable. Investigation often reveals the fact that such cases have had diagnoses and have been spreaders of tubercle bacilli for months and even years. As health officer of Berkeley, California, in 1925, Dr. W. P. Shepard sent to the practitioners of medicine in Berkeley the following excellent reasons why they should report tuberculosis:

I. It is an infecious disease. It may become infectious at intervals for many years. The tuberculosis patient is notoriously fickle in his choice of medical attendance. He may remain a menace to the community for many years after numerous attending physicians have been discharged. He therefore belongs to a category with the typhoid and diphtheria carrier and becomes subject to regulation by law whenever his acts endanger the community.

II. The Health Department "stands by" in order to:

1. Assist the physician to obtain continued cooperation from his patient.
2. See that all physician's instructions to the patient are such that the community is given maximum protection.
3. Assist the physician to obtain institutional care for the patient when desired.

4. See that the patient at no time becomes a public menace whenever he is not under competent medical care.
5. See that the exposed members of the family are carefully examined and observed in the hope of detecting the secondary cases in their incipient and curable stage.

III. The Health Department in no way contemplates interference with private physicians, disturbing the patient's confidence in his physician, making any statement to the family not approved by the physician, divulging confidential matters relating to the patient, or, in fact, doing anything to which the physician who is well versed in all aspects of tuberculosis could possibly object. *Reportable cases* are those who by their clinical findings appear to be *active cases,* whether the sputum is negative or positive.

IV. Educating the public to regard tuberculosis as a community problem is a necessity. Such education can be done effectively by a public agency having reliable information on the morbidity and mortality trends in the community over a period of years. Such information can only be obtained by coöperation between physicians and the Health Department.

V. This campaign by public agencies coöperating with private physicians to teach early recognition of tuberculosis, the proper means of preventing infection, the value of sanatorium care, the importance of hygienic living has resulted in the greatest medical triumph of this generation; namely, the lowering of the tuberculosis death rate by more than one-half.

BICHLORIDOL

Bichloridol is a proprietary preparation of corrosive mercuric chloride suspended in a "palmitin" base, intended for intramuscular administration. It is sold in compressible ampules called collapsules. This preparation was formerly marketed by the H. A. Metz Laboratories, Inc., but is now marketed by the Duke Laboratories, Inc. In 1925 the Council on Pharmacy and Chemistry rejected Bichloridol because it was marketed with indefinite statements of composition and under a non-descriptive name. The A. M. A. Chemical Laboratory reports that it analyzed Bichloridol because of inquiries received, one inquirer writing, "One-half to one grain a week gives practically no reaction and likewise mighty little therapeutic effect." The Laboratory found the preparation to contain only from one-fifth to one-tenth of the mercuric chloride claimed. The Laboratory points out that a discrepancy of this magnitude is inexcusable and comments on the desirability of physicians confining their use of proprietary preparations to products accepted for New and Non-official Remedies. (Jour. A. M. A., December 21, 1929, p. 1971.)

TUCKER'S ASTHMA SPECIFIC

The continued exploitation of this cocaine mixture is a standing disgrace to the federal authorities. The nostrum carries a label admitting the presence of 5 grains of cocaine to the fluid ounce. When the Commissioner of Internal Revenue was asked in 1922 how such a product could be sent without violating the Harrison Narcotic Law, his reply was that the cocaine in the remedy became hydrolyzed before it reached the public, and that when used there was either no cocaine or a very small quantity. This commissioner, at the same time, also gave a fulsome puff for the nostrum, expressing the opinion that the mail-order distribution of this product served "a great humanitarian cause" and, for that reason, the Treasury Department was taking no action. This in spite of the fact that the product obviously violates the Harrison Narcotic Law, for if it does not actually contain cocaine it admittedly contains a derivative of cocaine, to which the law also applies. Furthermore, if the product does not contain 5 grains of cocaine to the ounce, then it violates the National Food and Drugs Act. (Jour. A. M. A., December 7, 1929, p. 1829.)

THE INCIDENCE OF TUBERCULOUS INFECTION IN SCHOOL CHILDREN*

Russell H. Frost, M.D.
Wabasha, Minnesota

IT is a well known fact that figures once quoted to show that the majority of children of school age have become infected with the tubercle bacillus are no longer accurate; or that while they may apply in certain of the large European and American cities they do not now, if they ever have in the past, reflect with any degree of precision conditions as they exist in the average American rural or semi-rural community. No attempt will be made in this brief report to review the extensive literature on this subject, since all of us are familiar in a general way with the work of von Pirquet,[1] Hamburger and Monti,[2] Barchetti,[3] and Peiser[4] in Europe, Ferguson,[5] Armstrong,[6] Chadwick,[7] and Myers[8] in North America, as well as a host of others who found, upon the application of various cutaneous tuberculin tests, incidences of infection among children ranging from 41 to 94 per cent. One cannot but come to the conclusion, after even a cursory review of the numerous articles on the subject, that the extent of tuberculous infection among children in the various countries and cities is dependent upon a number of factors, among which must be social and living conditions in general and the amount of open tuberculosis in the community; that the amount of such infection probably varies greatly among the different social levels in the same community; and that any conclusions based upon the findings in any single city or social class and which would appear to prove that tuberculous infection is practically universal among adults are erroneous.

Unfortunately, little investigation of this sort has been carried on in Minnesota outside of the larger cities. Slater (9) in 1924 published a report of 1654 Pirquet tests made on school children in rural Southwestern Minnesota, among whom he found only 10 per cent to react positively. More recently Mattill and Fenger (10) have reported a series of 3011 Pirquets on children in rural Hennepin County, Minnesota, with positive reactors averaging 10 per cent (and 23 per cent if the questionable positives were included), these figures including several of the sizeable urban centers immediately adjoining the city of Minneapolis where Myers and his associates at the Lymanhurst School have found the incidence of positive Pirquets among school children to range between 45 per cent and 50 per cent.

TABLE I

TABULATION OF RESULTS OF VON PIRQUET TESTS

Age	Male		Female		Total of All in Age Group	Positive	Negative	Per Cent Pos.

Total	51	172	57	202	482	108	374	22.4%

This report gives the findings in 482 children in the public and parochial schools of Wabasha, Minnesota, a community of approximately 2500 persons. During the past school year the work was initiated by sending to the parents of each child a questionnaire asking for information about such of the child's past illnesses as might have a bearing upon the present problem and about a history of possible or actual exposure to open cases of tuberculosis. A check of the answers thus obtained showed that about the only reliable information secured was the child's name and age. In so many proved instances parents refused to admit that there had been cases of open tuberculosis in their families or homes that any attempt to correlate incidence of tuberculous infection with history of exposure had to be abandoned. The 482 children examined consti-

*Read before the sixty-first annual meeting of the Wabasha County Medical Society, Wabasha, Minnesota, July 11, 1929.

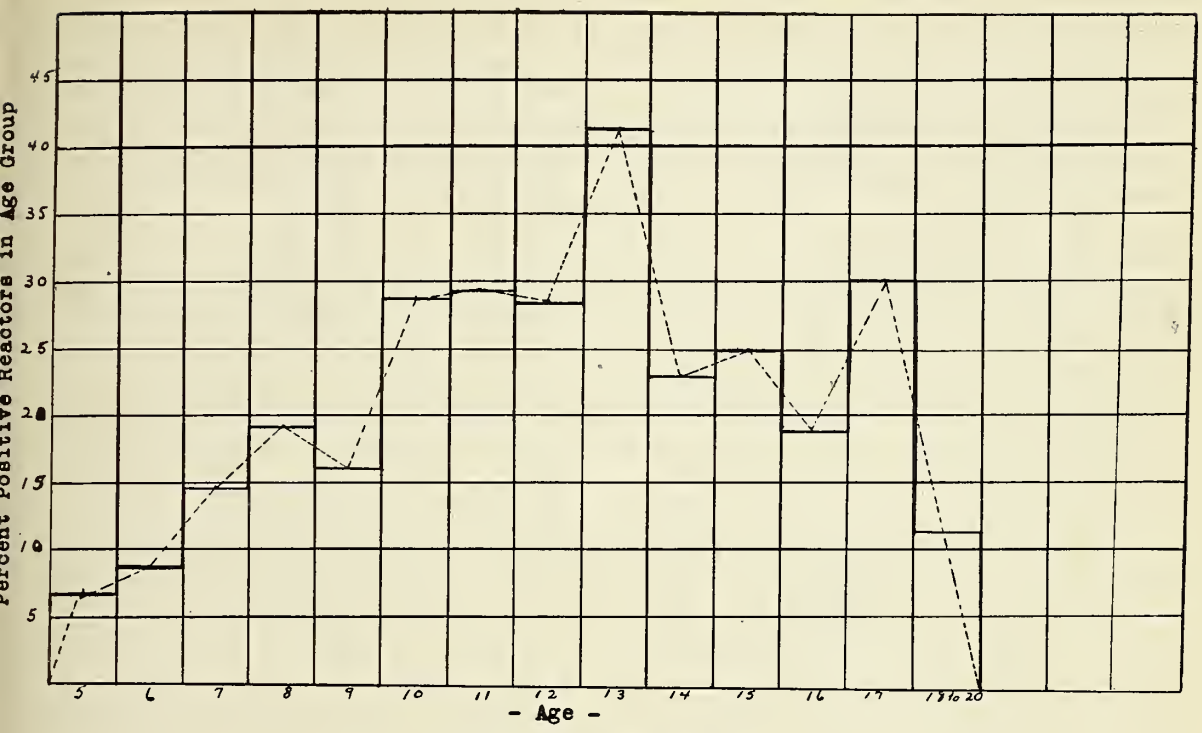

Fig. 1. Von Pirquet tests.

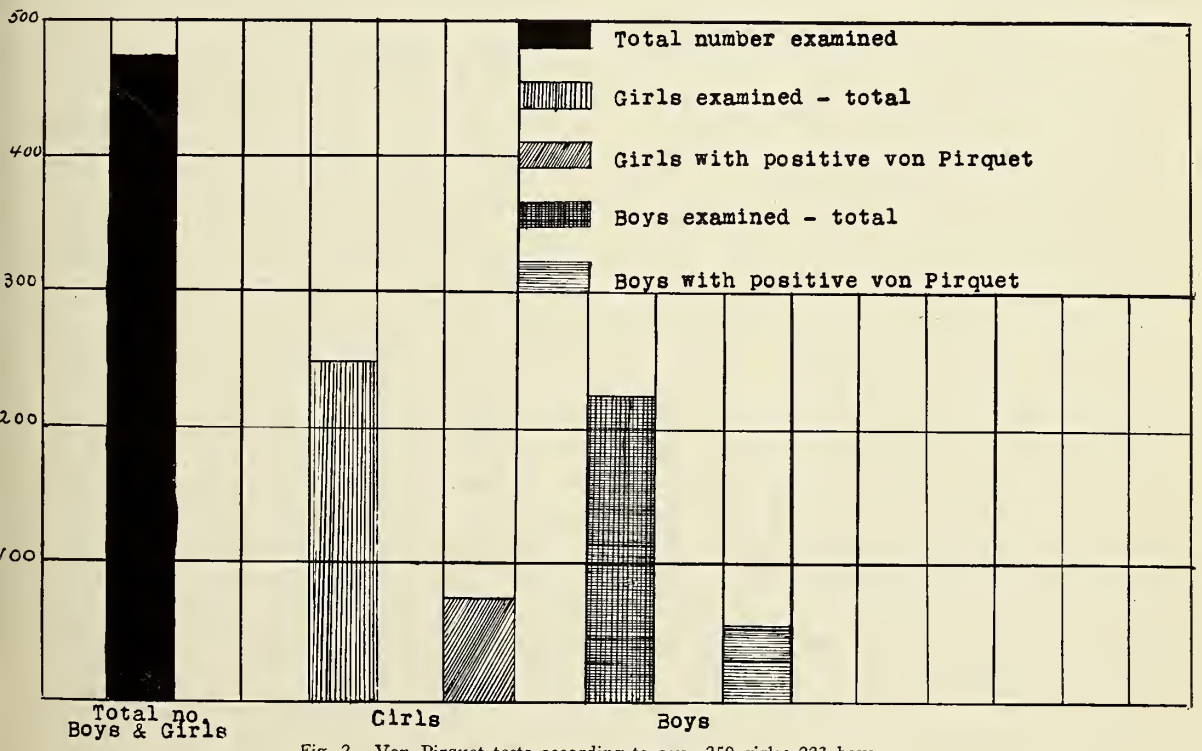

Fig. 2. Von Pirquet tests according to sex—259 girls; 223 boys

tuted approximately 80 per cent of the combined enrollment of the city's two school systems. A single von Pirquet test, read in forty-eight hours, was applied to each child, using the ordinary von Pirquet scarifier and full strength human O.T. of proved potency obtained from the Trudeau Laboratory at Saranac Lake, N. Y. I am aware that the results thus obtained can justifiably be criticized on the grounds that the von Pirquet at its best is only about 85 per cent accurate (11); that it would have been better to apply the graduated Mantoux or intracutaneous test with both human and bovine tuberculin; and that a certain small percentage of the negative reactors would have reacted positively had another von Pirquet been later applied. For various reasons, however, neither of these latter procedures was feasible, and it was felt that the results which were obtained and analyzed were sufficiently accurate for purposes of comparison with those obtained elsewhere, since in most other similar series approximately the same method of examination was employed. No effort was made to grade the positive reactions as mild, moderate or severe as is sometimes done; however, no reaction was regarded as positive unless there was at least a palpable red infiltration 5 mm. in diameter at the site of inoculation.

Of the 482 children examined, 223 were boys and 259 were girls. Their ages ranged from 5 to 20 years and the number of individuals in each age group was fairly uniform with the exception of the very youngest and very oldest. Of the total number 22.4 per cent reacted positively, these being remarkably uniformly distributed between boys and girls, 22.8 and 22 per cent respectively.

In common with many of the published reports of this nature and as will be seen in the table and shown graphically in the charts, the percentage of positive reactions rises fairly uniformly from 6+ in age group 5 to a peak of 41 per cent in age group 13, and then declines somewhat less consistently in the later age groups. Beyond the fact that one is unwarranted in making generalizations based upon a relatively small series of cases, with the errors inevitably attendant upon such an attempt, I can offer no explanation for this decline in the age groups from fourteen years on unless it be, as has often been suggested, that the skin hypersensitiveness to tuberculin in persons receiving a relatively slight infection very early in life tends to disappear as the primary tuberculous focus absorbs or calcifies with the passing of years or becomes more and more firmly invested with impenetrable layers of fibrous tissue.

It is hoped at a later time to incorporate with this preliminary report the findings after *x*-ray of the chests of the positive reactors in this group of children in order to determine the incidence of demonstrable roentgenographic evidence of primary pulmonary tuberculous infection, juvenile or hilum tuberculosis in the younger individuals, and adult type pulmonary tuberculous disease in those who are approaching maturity.

THE TEACHINGS OF MEDICAL EXPERIENCE*

George Douglas Head, M.D.
Minneapolis

THIS talk is directed to the young men upon the benches before me. Those veteran practitioners who may listen will travel in their mind's eye over the trying situations in their years of past experiences. To them it will be a recital of the lessons learned out of the practice of the healing art.

Efforts made to guide the young practitioner in a safe course of conduct fail to take into account the fact that a large part of his work will consist in the care of functional ailments for which there is no known pathology. A lack of training in the art of medicine causes him to flounder about in a sea of uncertainties which in the early years prove to be very costly. If a few of these errors can be avoided some gain will result. I know you will pardon personal references to my own work which can not be well avoided in illustration of the points which I wish to emphasize.

We are not all moulded of a like personality. Some of us by nature have a large amount of patience, others are of more irritable temperament. Some of us radiate hope and good cheer, others are more serious or fail to inspire our patients with a sense of reassurance.

The young man of irritable temper must overcome it if he would succeed. Pain and sickness produce a profound effect upon the human organism. Bodily functions are altered, internal secretions modified, sleep disturbed. The sick man or woman is on edge nervously. Tranquility of spirit is a golden asset in the face of such a situation. If possessed by nature, the young doctor is fortunate indeed; if not, it must be acquired by rigid discipline. Knowledge of disease in all its varying aspects is important to know but does not by any means fit a man for practice. Sick people are self-centered and serious about their ailments. They rely completely upon their medical advisor. He must be a patient, resourceful man, able to meet the varying demands made for relief from fancied as well as organic ills. He must be able not only to intelligently prescribe drugs or other therapeutic measures but must give out of his own self that reassurance that comfort of mind required of all those engaged in the care of the sick.

One of the first lessons which a young man must learn is to avoid dogmatic statements relative to the prognosis of disease. Some patients apparently going down to death ultimately recover; others apparently affected with a mild sickness die unexpectedly. Many years ago when I first began the practice of medicine I had an experience which I shall never forget. A nurse about forty years of age was down with lobar pneumonia. She was in the hands of a very skillful man. A number of consultants had seen her. In a state of deep coma for days with high fever, deep cyanosis and no expectoration, a fatal prognosis was made. The friends and others were awaiting her death. To the surprise of us all she refused to die and after a fearful struggle recovered. It does not add to a man's professional reputation to make a fatal prognosis and have the patient survive.

Where the diagnosis is established or highly probable do not hesitate to express your opinion as to the outcome, always, however, with the qualifying statement that "experience is fallacious and judgment difficult." Many times in such a situation "Silence is golden." On the other hand, to say nothing to enquiring friends when the situation demands an opinion is a sign of lack of self-confidence and an evidence of weakness. Sometimes it is better to be wrong and be positive rather than to be right and say nothing. It is important to sense the situation.

When pressed for a diagnosis where a definite conclusion can not be arrived at, state that more time and study are required. Do not say you do not know. An older man whose reputation has been established in the community can admit his ignorance. Not so a young practitioner. A diagnosis is usually an opinion. It is rarely proven beyond some doubt. In an obscure case where a conclusion is difficult seek time for further investigation. The best rule of good prac-

*A Talk delivered before the Medical Alumni Association of the University of Minnesota.

tice is to investigate and again seek more evidence.

The course of certain diseases is very difficult to interpret. One of these is lobar pneumonia. It is very treacherous. I have learned never to give a positive opinion as to the outcome in a given case. Two personal experiences have taught this lesson. Some years ago while studying in Vienna, I was assigned to examine a young man propped up in bed, rather cyanotic, breathing with an effort and rapidly. A cursory examination revealed lobar pneumonia of the left upper lobe. His pulse was regular, he was rational and his heart sounds were good. Having finished the examination I sat down on the edge of the bed and started talking with a doctor examining a case next to mine. Suddenly I felt a sort of tremor in the bed and looking at my patient saw him with his head back, pupils dilated and an ashen gray color over his face. He was dying. So sudden had been his death that a sandwich which he had been eating was still in his fingers and some of the bread in his mouth. Examination of his heart five minutes prior to death gave no inkling of the fatal outcome. Not many years ago while on a consultation in South Dakota I examined a large robust man about fifty-five years of age with lobar pneumonia. He was a very sick man but his heart tones were of good quality and there was no irregularity. I saw no sign of approaching death. After finishing the clinical study I stepped out of the house, walked about half a block up the street when the nurse came running toward me saying, "come quick, Doctor, the man is dying." Sure enough, on my return, not five minutes after I had examined him and found no signs of a failing heart, he was dead.

If the patient has a fatal malady it is not good practice to tell the patient himself but make known his condition to some discreet member of his family. No more difficult situation arises in the sick room than to face day after day a conscious patient suffering with an incurable disease who is going to die and knows it himself. The atmosphere is intolerable. In the face of death, instill a fighting spirit in the patient and let him go down with his colors flying. Not long ago a man with an incurable abscess of the liver and thrombophlebitis lay dying. His wife came to me and said, "Now, Doctor, my husband is going to die. What is the use of all these measures of treatment which you doctors are carrying on. Why not let him die in peace." "Yes," I said, "we think he is going to die but he is perfectly rational and if we relax our efforts he will be quick to interpret that we have given up hope. Let us give him courage to face death," and we did. He went to the end fighting like the good soldier that he was.

On the other hand patients at death's door and unconscious of their fate have a right to die in peace. Futile attempts at keeping them alive by various forms of medication are not justified. Put the dying patient in the arms of Morpheus with a hypodermic of morphine and let him sleep out his existence. It relieves the patient of suffering and calms the relatives in the presence of death.

Do not be too anxious to state your opinion of the nature of a case unless pressed for your conclusion. Delay in stating a diagnosis often saves mistakes, the later course of the disease changing one's opinion. In every case acquire the habit of painstaking investigation. Gerhardt's words should not be forgotten, "Die frucht der Heilung wachts am Baume der Erkentniss. Ohne Diagnostik Keine vernünftige Therapie. Erst untersuchen dann urteilen dann helfen."

When all the clinical evidence points to a diagnosis which seems correct beyond doubt, but is reached by little investigation and an easy course of reasoning, be cautious about stating your conclusion too positively. Many apparently certain diagnoses prove at the operating or autopsy table to be wrong. As a rule the more carefully you have investigated all features of your case the more nearly correct will be your conclusions.

The signs of the certain approach of death are sometimes very difficult to interpret. It is a good rule to be very slow in making a dogmatic statement when faced with such a decision. Not long ago I had this experience. A very sick man with a chronic ailment was suddenly seized with what appeared to be an acute heart failure. He was unconscious, eyes turned back in his head, pupils widely dilated, face ashen gray color, whole body deeply cyanosed, no pulse at the wrist, heart sounds could not be detected with the stethoscope. To all appearances he was dying. The family was summoned to the bed side and informed of approaching death but the patient did not die. After some stimulation the heart began beating, the pulse returned, consciousness

was restored and he lived on for three weeks more, to the chagrin of his medical attendant and the disturbed mental state of his family.

I have learned not to ask for an autopsy in a fatal case, by telephone or proxy. If you want it badly make your request in person. You are the attending physician and friends will often grant a request from you which would be refused another.

Never talk to friends about an autopsy in an apparently fatal case prior to death. It makes a bad impression. Wait until the patient is gone; then ask for the postmortem examination.

Always secure an autopsy when it is possible. It is the best way to learn clinical medicine. A well performed postmortem always reveals valuable lessons not to be forgotten. One learns most by his mistakes. Some men prefer not to know them; not so the careful clinician.

In a difficult case court consultation. The family is reassured and often a new viewpoint is revealed and valuable therapeutic suggestions brought out. No man has experience enough or knowledge enough to know everything in medicine. The more experience one accumulates the more humble he becomes and the less he thinks he knows.

Where a difference of opinion occurs between the man in attendance on the case and the consultant, the attending clinician should weigh carefully the reasons for the consultant's opinion but should not necessarily follow the advice given if his own judgment dictates otherwise. The responsibility for the outcome of the case rests on the attending man's shoulders. Often times the medical attendant in close touch with the case who has followed its course from day to day has the better judgment. Not long ago in a severe heart case such a difference of opinion arose. The attending man demurred at the advice given by the consultant. However, he gave way to the consultant's supposedly better skill and experience. The result was disastrous to the patient.

The atmosphere of the sick room should always be hopeful. There is enough anxiety on the part of relatives without adding to it with a long face. On the other hand good judgment must be shown in not assuming too frivolous or joking an attitude in the face of a grave situation. In these situations good common sense should be shown.

In dealing with people harboring chronic ailments much resourcefulness must be called into play. The profession has been slow to teach its young men the best methods of procedure when dealing with such diseases. Altogether too much emphasis in medical instruction has been placed upon the management of acute diseases. A doctor should as a rule take the attitude of an advisor or counselor rather than a policeman or sheriff.

Sick men or women can be reasoned into a course of action but rarely forced or driven into it. Place some responsibility upon the patient himself. It is his body. If he does not heed your advice he is the one to suffer. Put to him in this light he will often acquiesce where otherwise he would rebel.

Attention to details in instructions to patients is very important. Here many men young and old fail. All bedside orders should be in writing. It is your protection, impresses the patient with their importance, tends to make instructions more specific and avoids confusion or misunderstanding on the part of nurses.

Carefully recorded notes upon the findings of your cases, not only the primary examination but also the subsequent visits should always be kept. Nothing impresses a patient more than a good record of his case kept on file and referred to whenever he consults you. No man has a sufficiently retentative memory to carry the details of complaints and findings. To ask patients from visit to visit for a recital of their aches and pains, medicine taken, etc., consumes time and impresses badly the sick man or woman.

Do not waste time in idle gossip in the sick room. So soon as you have finished your examination and written your orders leave the patient with some cheering word of hope and comfort.

I have seen a doctor enter a house and without any solicitous inquiry concerning his patient start a discussion relative to the model of his latest automobile or the coming football game. Your first consideration should always be the condition of the sick person. Has the patient had a good night? How high did the fever range? Was the pain better or worse? Your time is too valuable. You have too many other sick people to visit to bother about unimportant things in the presence of suffering and death.

Perfect your knowledge in the natural course of disease. Both operative and medical treat-

ment is overestimated. It is astonishing how well many sick people will get on if they are left alone and not fussed with too much. The old rule in rhetoric applies to therapeutics "Be not the first by which the new is tried nor yet the last to lay the old aside." It takes a long time to establish the value of a therapeutic procedure or a scientific truth. In our reasoning we as scientific men must not lose sight of the rules governing scientific evidence. Remember that many diseases are self-limited. Our zeal to treat disease functionally often leads us to lose sight of the known organic pathology of many ailments worked out over years or centuries of painstaking observation.

In the hope that some of you young men may profit thereby I have opened up the book of my experience and turned some of its leaves. Great progress has been made in the control and cure of disease in the third of a century just passed. It is a work of which all medical men can be justly proud. We must, however, sit humbly at the feet of the Goddess of our science when we remember our failures to conquer cancer in its various forms, tuberculosis, pneumonia, nephritis, rheumatic fever, scarlet fever, chorea, septicemia, erysipelas, influenza, whooping cough, measles, leukemia, and a host of other diseases which suffering humanity is called upon to face. These stand as a challenge to the present generation of physicians.

ZONITE DECLARED MISBRANDED

Zonite is another of the many hypochlorite preparations which arose from the work of Carrel and Dakin during the war. It has been advertised like a typical "patent medicine" under the firm name of the Zonite Products Co. The propaganda for Zonite is, in effect, capitalization on the work of Carrel, Dakin and others, and the method of exploitation has been that typical of the nostrum business. Chemically, Zonite, after dilution with equal parts of water, is claimed to be essentially the same as surgical solution of chlorinated soda. According to a recent notice of judgment, Zonite was declared misbranded in that certain statements were false and misleading. Zonite has been exploited to both the physician and the public. It goes without saying that it has not been accepted by the Council on Pharmacy and Chemistry for inclusion in New and Nonofficial Remedies. (Jour. A. M. A., December 7, 1929, p. 1830.)

THE HAZARD OF USING NONACCEPTED DRUGS

Recently the A. M. A. Chemical Laboratory published a report on Bichloridol collapsules indicating that only from one tenth to one fifth of the amount of mercuric chloride claimed to be present was actually discovered. The results of the A. M. A. Chemical Laboratory has received independent confirmation. Apparently most of the mercuric chloride had reacted with the lining of the collapsule and was not in the medicament itself. This product has been administered to patients by physicians who thought that they were giving a certain dosage of mercuric chloride, whereas the patient received only from one tenth to one fifth of the dose he should have had. In 1925, the Council on Pharmacy and Chemistry declared Bichloridol nonacceptable for New and Nonofficial Remedies. It is safer to follow the Council! (Jour. A. M. A., February 22, 1930, p. 563.)

THE USE OF BARBITURIC ACIDS, ACETYLENE, SPINAL ANESTHESIA, TRIBROMETHYL ALCOHOL AND OTHER ANESTHETICS IN THE MAYO CLINIC IN 1929*

JOHN S. LUNDY, M.D.
Rochester, Minnesota

THIS is the fifth of a series of articles,[2, 3, 4, 6] dealing with results from the use of various anesthetic agents as they have been used in The Mayo Clinic through each of the five years.

The data presented in Tables 1 and 2 will be referred to briefly and in the same manner as those employed in 1927 and 1928. I would point out that Table 1 is arranged from a slightly different standpoint than that adopted in the arrangement of Table 2. In Table 1, the total of the percentages for the respective years is 100. The percentages in Table 2 total more than 100 for the reason that in some cases several agents, such as a local anesthetic, one of the barbituric acids, and inhalation anesthetics were used during a single operation. A single case, in Table 2, therefore, must be included under several headings.

TABLE 1

ALL AGENTS OR METHODS USED (EACH FIGURE IN THE TABLE REPRESENTS THE NUMBER OF INDIVIDUAL CASES FOR THE YEAR DIVIDED BY THE TOTAL NUMBER OF CASES FOR THE YEAR)

Agents	1929 Per cent	1928 Per cent
Local*	36.2	40.39
Local and ether	0.18	0.26
Local and gases†	8.0	9.96
Spinal‡	5.19	1.21
Ether (semi-open drop method)	15.2	16.75
Gases†	31.0	30.13
Ethyl chloride†	0.71	0.73
Oil-ether colonic	0.57	0.58
Acetylene	0.22	0.06
Barbituric acids	3.04	
Tribromethyl alcohol	0.06	

*Includes the local anesthetic used for extraction of teeth, thyroidectomy, tonsillectomy, hemorrhoidectomy, and so forth.
†With or without ether.
‡With or without general anesthesia.

LOCAL ANESTHESIA

The data show a decrease in the percentage of patients to whom local anesthetics were given. However, this decrease has been principally in the number of cases in which infiltration anesthesia has been accomplished by the surgeon or his assistant, mostly for minor surgical operations. There was also a slight decrease in the number of cases in which local and general anesthesia were intentionaly or necessarily combined. On the other hand, there was a considerable increase in the use of spinal anesthesia; it was used more than four times as frequently in 1929 as in 1928. This form of anesthesia was used by many surgeons rather than by a few. A factor contributing to the more extensive use of spinal anesthesia was its wide use in urologic cases for a period of six or seven months of the year. However, the conclusion was reached that it was not applicable as a routine measure and that henceforth it would be used only when indicated.

Spinal anesthesia continues to remain popular for preparing patients for operations for lesions of the large bowel. The majority of such patients is given this type of anesthetic unless there is a contraindication to its use; the principal contraindication is hypotension for frequently they are debilitated. The use of ephedrine, prior to the administration of spinal anesthesia, has been continued throughout the year with considerable satisfaction. I believe that ephedrine is valuable as a means of offsetting the fall in blood pressure which may accompany spinal anesthesia. Therefore, I feel that in the average patient with an average blood pressure, ephedrine sulphate,

TABLE 2

AGENTS OF SPECIAL INTEREST (PERCENTAGE OF CASES IN WHICH CERTAIN ANESTHETIC AGENTS OR METHODS WERE USED, BOTH ALONE AND IN COMBINATION WITH OTHERS)

Agent	1929 Per cent	1928 Per cent
Local	49.9	51.8
Ether	43.6	44.6
Ethylene	27.2	30.9
Nitrous oxide	34.0	27.9
Carbon dioxide*	39.4	32.5
Acetylene	0.22	0.06
Barbituric acids	3.04	
Tribromethyl alcohol	0.06	

*Used as a respiratory stimulant only.

*From the Section on Anesthesia, The Mayo Clinic, Rochester, Minnesota. Read before the Ramsey County Medical Society, St. Paul, Minnesota, February 5, 1930.

0.050 gm., should be given subcutaneously about ten or fifteen minutes prior to the administration of a moderate dose of procaine hydrochloride introduced subdurally. I believe that if the blood pressure is in the neighborhood of 100 mm. of mercury, systolic, the ephedrine should be given twenty minutes before the spinal injection is begun and that a spinal anesthetic should not be given unless there is some evidence that the patient can respond to a drug which will raise blood pressure. In patients with hypertension, when the blood pressure is 160 mm. or more, systolic, the hypodermic injection of ephedrine is delayed until the procaine has been placed subdurally, and the effect of the procaine is apparent (sensation of heat or of numbness in the feet). Obviously, the important factor, when a patient has hypertension, is to delay giving the ephedrine, with its effect of elevating the blood pressure, until it is certain that anesthesia can be produced with the procaine. There is always the possibility that one cannot make a proper subdural deposit of the procaine.

Toward the end of 1929 there was an increasing tendency toward the use of spinal anesthesia in certain operations in the upper part of the abdomen, especially operations on the gallbladder and its ducts. I had felt that untoward reactions were occurring less frequently in 1928 than previously and that the severity of these reactions had decreased, and I had hoped in 1929 to find some satisfactory means of increasing the duration of anesthesia without increasing the number and severity of untoward reactions. At present, I believe that one is not justified in using, in the average case, a larger dose of procaine than is considered to be a safe one after the various factors by which the dosage is determined have been taken into consideration. I consider, therefore, that in estimating the dose to be used, one should not often exceed a dose of 0.001 gm. of procaine for each pound of body weight, and should not exceed 0.150 to 0.30 gm. for any patient. I have seldom exceeded a dose of 0.20 gm. and then seldom have seen any special untoward result. Nevertheless, since all anesthetic agents have the power to destroy life as well as to produce anesthesia, I think it wiser to use a moderate dose of procaine, and, if necessary, to combine procaine with some other anesthetic agent (combined anesthesia). In debilitated or old patients, patients with hypotension, with heart disease, with recent extreme loss of weight or decreased respiratory surface or patients with several types of infection, even as much as the usual dose might be contraindicated. In such cases I feel that not more than 0.10 gm. of procaine will prove to be a safer dose. I believe that it is often especially valuable to give morphine sulphate, grain ¼ (0.016 gm.) subcutaneously and sodium *iso*-amylethyl barbituric acid, grains 6 to 9 (0.40 to 0.50 gm.) by mouth as preliminary medication. In this way it is possible to produce anesthesia with smaller doses of procaine administered subdurally than when less preliminary medication has been used.

Although I have frequently attempted to obtain ampules of procaine with some type of nonremovable indicator showing the number of milligrams of procaine contained in the ampule, I am told by manufacturers that this cannot be done. Therefore, in order to avoid error after the labels have been removed from the ampules during the process of sterilization, I have found it desirable to use an ampule holder. The ampule holder bears a mark which indicates the number of milligrams of procaine in the ampule. This eliminates the possibility of giving an overdose by using the wrong ampule (Fig. 1). On the tray the nurse places three holders which contain, respectively, one ampule containing 0.10 gm., one containing 0.120 gm. and one containing 0.150 gm. Moreover, the ampule may become slippery, and the holder prevents its being dropped.

A second point of importance in the application of spinal anesthesia, after the dose has been determined, is the technic to be followed in the administration of the anesthetic. The method employed in the last year has produced rather satisfactory results. I believe that it is a good technic for institutional use, and especially when one may wish to direct another in the administration of a spinal anesthetic. For example, a surgeon should be able to direct his assistants in the manner in which the anesthetic is to be given. He may even wish to give directions verbally or by letter. I feel that if an exact technic such as I shall describe could be followed by several groups, comparison could then be made at the termination of the year which would point out the important factors in obtaining spinal anesthesia without untoward reaction.

There are four important factors in the administration of a spinal anesthetic: 1. The site of injection may be (a) between the second and

third lumbar vertebræ for operations in the upper part of the abdomen; (b) between the third and fourth lumbar vertebræ for operations in the lower part of the abdomen; (c) between the fourth and fifth lumbar vertebræ for operations on the perineum and lower extremities. 2. I have already explained how I estimate the dose. 3. The amount of spinal fluid to be withdrawn

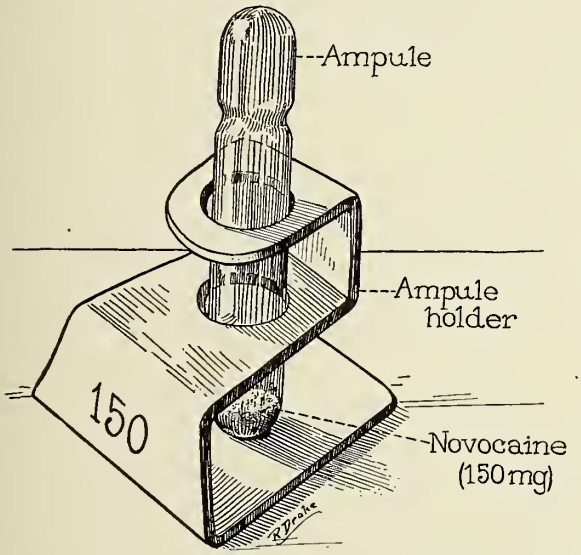

Fig. 1. Ampule holder holding ampule of procaine. The figure on the ampule holder indicates in milligrams the weight of procaine in the ampule.

and in which the crystals of procaine will be dissolved and then reintroduced will vary with different regions. I find that for most operations in the lower half of the abdomen, especially those in the urinary bladder or those in which penetration through the urinary bladder is necessary, withdrawal of about 3 c.c. of spinal fluid is sufficient. For operations on the colon withdrawal of 4 to 5 c.c. is satisfactory. For operations on the gallbladder and its ducts withdrawal of about 6 to 7 c.c. of fluid is sufficient. For operations on the stomach it is best to withdraw from 7 to 8 c.c. 4. The speed with which the fluid is to be injected is important. I believe that the most satisfactory results from procaine are obtained by injecting 1 c.c. of fluid every two seconds if the spinal fluid aspirates freely. In other words, injection of 4 c.c. of fluid will be accomplished in eight seconds.

From what has been said concerning dose and withdrawal of spinal fluid, the following facts can be deduced: 1. Exclusive of differences dependent on the intervertebral space that is used for injection, the level of the anesthetized space will be relatively high if a relatively large volume of spinal fluid is withdrawn, used as a solvent for the anesthetic drug and then reinjected; relatively low, if the volume of spinal fluid employed is relatively small. 2. For operations of average length, the dose will vary directly with the size and tolerance of the patient.

I am still very much impressed with the value of giving oxygen or a mixture of oxygen and carbon dioxide to patients in whom untoward reactions seem to be developing. It is decidedly advantageous in controlling nausea and vomiting regardless of whether or not untoward reaction is apparent. I consider that we have obtained satisfactory results from the use of spinal anesthesia. A detailed account of many of its uses has been prepared.[9, 10]

Combined anesthesia has been decreasing somewhat in popularity for the last four years. I believe this to be due to the interest which has been shown in the use of these new anesthetic agents. However, the probable ultimate outcome of the use of these new anesthetics will be a tendency to revive the popularity of combined anesthesia. These new agents will be used as part of the preliminary medication in preparing patients for operation. It seems that their most logical use is in balanced anesthesia.

ETHER (SEMI-OPEN DROP METHOD)

The usual annual decrease of about 1 per cent in the number of cases in which ether has been administered by the semi-open drop method, continues to be evident in the data for 1929. I believe that this decrease is due to the employment of new anesthetics, the use of which was begun in 1929. This small annual decrease will be especially interesting to those who had expected the use of ether by this method to be short-lived. There is, however, one outstanding drawback in the gradual abandonment of this method. Namely, if the popularity of this method decreases, anesthetists will become less skillful in its use and it is probably the safest method of producing anesthesia in the hands of the average anesthetist. At least, one often feels justified in using it when there might be a question con-

cerning the advisability of using other general anesthetic agents.

OIL-ETHER COLONIC ANESTHESIA

Oil-ether colonic anesthesia is now used only in obstetric cases and then only when it seems to be particularly indicated. It has been almost entirely replaced by the intratracheal method in surgical operations.

ETHYL CHLORIDE

Ethyl chloride, as an inhalation anesthetic, is used occasionally and almost entirely for induction to ether. Recent reports of its unsatisfactory use elsewhere has interfered with its popularity at the clinic. However, in my experience, satisfactory results have been obtained with it.

INTRATRACHEAL ANESTHESIA

From the standpoint of the anesthetist, intratracheal anesthesia is one of the most desirable methods. Personally, I am impressed with its advantages and hope to see it used more extensively in general surgery. In 1929, as well as during 1928, it was used almost entirely for operations on the head, neck or thorax.

During 1929 I used the two-catheter technic. The anesthetic vapor was insufflated through a small catheter and was exhaled through a larger catheter. The larger catheter was connected by a rubber hose to a rebreathing bag, and satisfactory anesthesia resulted in almost every case. In cases in which operation was to be done on the nose, and the operation permitted, catheters were passed through the mouth. When operation was to be done on the mouth or lower lip, the catheters were passed through the nose. In 1930 I hope in some cases to be able to utilize a single large catheter with an inflatable cuff by means of which the parts of the trachea about the catheter may be entirely closed off. This is desirable from the standpoint of excluding air from the anesthetic mixture and preventing aspiration of mucus.

CARBON DIOXIDE

Carbon dioxide continues to be a valuable asset, and the consensus of opinion of anesthetists at the clinic is that carbon dioxide should be available whenever an anesthetic is being administered. I also have found mixtures of carbon dioxide and oxygen to be of great benefit in attempting to control hiccough which had become persistent, both in surgical and in nonsurgical cases.

NITROUS OXIDE

Nitrous oxide continues its rather spectacular return to popularity. However, in many instances it is used only for induction, and at the termination of administration of ethylene. Nevertheless, I am finding that since carbon dioxide is available, ethylene is less necessary.

When intratracheal anesthesia is being used it is my custom to use nitrous oxide and oxygen as a vehicle for ether unless cautery or diathermy is being used in close proximity to the vapor, in which case ether is not used. Future changes in the popularity of nitrous oxide depend on the fear of explosion with ethylene. Should explosions of ethylene occur frequently throughout the country, or should one occur at the clinic, my associates and I probably would abandon its use and substitute nitrous oxide for it.

ETHYLENE

The use of ethylene has decreased about 3 per cent each year for the last three years. This is without doubt due to the frequent reports of explosions. Thus far, no explosions have occurred at the clinic, although it has been administered more than 37,000 times. Satisfactory results are obtained with it in the majority of instances, although in many cases it has been reënforced with ether so that anoxemia might be avoided.

ACETYLENE

The use of acetylene for thoracoplasty and less extensive operations on the thorax was begun in 1928. As I have stated before, it has been possible, with acetylene, to produce anesthesia and relaxation, with quiet breathing, without anoxemia and without the addition of ether. Acetylene was used more than three times as often in 1929 as in 1928; it was the anesthetic used as a routine for thoracoplasty and similar operations on the thorax. The results I have obtained in its use have been entirely satisfactory, except that the blood pressure is markedly elevated during the first twenty minutes of anesthesia. This elevation of blood pressure is almost a constant factor.[1] In anesthesia by acetylene I find it advantageous to give morphine shulphate and atropine sulphate subcutaneously prior to the administration of acetylene. There is said to be a greater possibility of explosion in the use of acet-

ylene than in the use of ethylene and I feel that if possible its use should be curtailed, if equally favorable results can be obtained in any other manner. At present, my associates and I plan to use it for thoracoplasty and other operations on the thorax in the presence of bronchiectasis. When bronchiectasis is absent, we may use morphine sulphate grain ¼ (0.016 gm.) subcutaneously, sodium *iso*-amylethyl barbituric acid 6 to 9 grains (0.40 to 0.60 gm.) by mouth, with ethylene or nitrous oxide and with mixtures of carbon dioxide and oxygen. We are still confronted with the difficulty of obtaining pure acetylene.

BARBITURIC ACIDS

The use of barbituric acids as hypnotics, antispasmodics, and anesthetics, has been rather extensive since April 1, 1929. Statistical data and reports of individual cases concerning our experience with these agents appear elsewhere.[5, 7]

Personally, I feel that barbituric acids serve us best when used to reënforce preliminary medication, with the idea of reducing the amount of inhalation anesthetic which will then be required in order to produce anesthesia, relaxation, and quiet respiration without anoxemia. We have used chloretone by mouth, morphine sulphate subcutaneously, and sodium *iso*-amylethyl barbituric acid intravenously and by mouth in preparing patients for operation. This combination has been very satisfactory from more than one point of view. Fear, excitement and the amount of anesthetic necessary are reduced. Frequently the nervous patient is quieted sufficiently so that a local anesthetic alone is all that is necessary. Because of the antispasmodic properties of *iso*-amylethyl barbituric acid, it protects the patient against the most toxic effects of a local anesthetic; namely, convulsions of the respiratory musculature and the resulting anoxemia. In 1929, it was used by mouth in more than 500 cases with satisfactory results. I have given it by rectum in capsules of 3 grains (0.20 gm.) to children and adults when oral and intravenous methods were contraindicated or exceedingly difficult to follow. Capsules given by rectum have been very satisfactory, especially in children. Unless the dose of the barbituric acid is 9 grains (0.60 gm.) or less, I prefer to give the drug intravenously.

In 1929, sodium *iso*-amylethyl barbituric acid was administered more than 600 times and almost standard technic has been adopted in its intravenous administration which is as follows:

A dose of sodium salt of *iso*-amylethyl barbituric acid is dissolved in sterile distilled water to make a 10 or 20 per cent solution and is aspirated into a 10 c.c. syringe. A very sharp needle is attached, and intravenous puncture is made. The drug is then injected, in the average case, at the rate of about 2 c.c. for each minute for the first 4 c.c. It is always injected much more slowly in old and debilitated patients, especially in the presence of hypotension. Readings of blood pressure are taken each minute during the administration of the drug. If the blood pressure is normal at the beginning, and then falls to a level of 85 or 90 mm., systolic, and remains low, the injection is discontinued and the needle is withdrawn.

As the anesthetic solution is being injected, the patient is asked questions. When he can no longer respond it is considered that the full hypnotic dose has been given, but even then little, if any, anesthesia has been produced. If, for any reason, it is desirable that anesthesia be produced with the barbituric acid alone, the injection is continued, and the degree of anesthesia is ascertained by grasping the skin with a skin forcep; if there is no response to this stimulus, traction on the skin with the forceps is added. If there is still no response to the stimulus, anesthesia is considered to be established. Then it remains only to decide how long it is desired that the anesthesia should last. If the operation is to be long, and it is desirable that the patient have prolonged sleep after the operation, the injection is continued until 4 to 6 grains (0.24 to 0.40 gm.) more of the drug have been given. Throughout the injection the depth of respiration must be constantly observed. If it becomes shallow, or stops at any time, the injection must also be stopped immediately and no further injection made until the respiration becomes reëtablished. An early untoward effect on respiration is almost always directly due to administration of the drug at an unduly rapid rate. In estimating the amount of the drug to be used in controlling nonsurgical patients who are excited or have some spasmodic disorder I expect to see some effect of the barbituric acid over as many hours as there were grains used. As the effect of the drug is wearing off, some patients will sleep, whereas others have simply a feeling of weariness.

In the average patient it can be expected that anesthesia will be maintained for twenty to forty minutes when a dose of 15 to 23 grains (1 to 1.5 gm.) has been used, provided the patient has been given a preliminary dose of chloretone grains 10 (0.65 gm.), by mouth, and morphine sulphate, grain 1/4 (0.016 gm.) with atropine sulphate grain 1/150 (0.0004 gm.) subcutaneously. In the majority of instances I have used sodium *iso*-amylethyl barbituric acid but I also have used sodium ethyl*iso*butyl barbituric acid in a few cases.

In reviewing the literature on the barbituric acids I find their outstanding disadvantages to be as follows: (1) postoperative pulmonary edema, and (2) excitement, which appears frequently and is very annoying unless some method of restraint is applied. On the other hand, patients to whom the drug has been given are so enthusiastic concerning it that a genuine effort should be made to use it in preparing patients for operation.

TRIBROMETHYL ALCOHOL

The new general anesthetic, tribromethyl alcohol (avertin or E-107) administered usually by rectum has been recommended very highly. Therefore I used it in a few cases in 1929. I was careful to give no more than 100 mg. for each kilogram of body weight and have prepared patients preoperatively with chloretone grains 10 (0.65 gm.) by mouth, morphine sulphate grains 1/4 (0.016 gm.), with atropine sulphate grain 1/150 (0.0004 gm.) subcutaneously. It was my intention to produce only basic anesthesia and to combine it with anesthesia by inhalation. Occasionally no other anesthetic was necessary and results were satisfactory. There have been reports of intestinal irritation resulting from the rectal use of tribromethyl alcohol and I was particularly concerned about a few cases in which patients complained of tender anus and rectum for a few days after operation. Proctoscopic examination, however, revealed no pathologic condition and each patient made an uneventful recovery. However, I believe my associates and I are not likely to use this drug in aqueous solution. If we use it at all, it will probably be in a solution of gum acacia and then only as a basic anesthetic.

ADENOMATOUS POLYPS OF THE COLON AND RECTUM*

HAROLD E. HULLSIEK, M.D., F.A.C.S.
Saint Paul

THE term adult, acquired polyp was first applied in 1925 to a certain class of pedunculated neoplasms found in the large bowel. Erdmann and Morris used this term as a clinical differentiation from the so-called multiple polyposis which is now accepted as a definite entity. The word polyp has a purely morphological application with no relation to histological characteristics. A polyp is merely any new-growth with a pedicle, and may be an adenoma, fibroma, lipoma, myoma, or angioma, and may be benign or malignant. There have been various attempts at clinical or pathological classifications of polyps, but they have been rather unsatisfactory. Lockhart-Mummery classifies the adenomata of the bowel as: (1) True multiple adenomata; (2) multiple polyps associated with old strictures of the colon; (3) polyps associated with hyperplastic tuberculosis; (4) polypoid condition resulting from ulcerative colitis.

The relation of polyps to mucous membrane irritation in the colon has long been well known. Single or scattered polyps, sometimes quite obviously the result of irritation, at other times with no discoverable etiological lesion, sometimes quiescent and discovered accidentally, at other times producing violent symptoms necessitating immediate attention, constitute the group called by Erdmann and Morris the adult, acquired type. It was suggested in a former paper that the term "adult" be discarded, using only the word "acquired," since the former carries the implication that this type of tumor is confined to adults and is not found in children. Adenomatous polyps make up by far the largest group of intestinal growths and are frequently seen in children.

In the second type of polyposis we find the mucosa of the bowel the seat of hundreds or thousands of small polypi (Fig. 1). Luschka estimated the number in his patient at 10,000. This form usually makes itself evident in childhood or early youth, rarely has a discoverable associated etiologic lesion, has a distinct familial tendency, and a milgnancy incidence of from 40 to 50 per cent. This form is the true multiple, adolescent, congenital polyposis, and is the only type to which the term multiple polyposis should be applied. A bowel may contain scattered and even fairly numerous polypi, and they may still

Fig. 1. Resected colon showing multiple polyposis.

be merely multiple polyps, and not a true multiple polyposis.

In a collection of 46,879 cases of rectal diseases of all types there were 554 instances of benign tumors. Dewis in 1904 collected from the literature 219 cases of benign tumors of the intestinal tract, all of which were submitted to careful microscopic examination. Leichenstern listed 128 intestinal polypi. Of the total 347 cases in the two series 243 were in the rectum and colon, and 202 were adenomata. The various histological types were distributed as follows:

TABLE 1

	Angio.	Fibro.	Myo.	Adeno.	Lipo.	Total
Colon	0	1	8	46	12	67
Rectum	2	2	10	156	6	176
	2	3	18	202	18	243

The following table from Erdmann and Morris illustrates the predilection of adenomatous tumors for the rectum and colon.

TABLE 2

	Small gut	Large gut	Rectum
Adenoma	11%	25.2%	63.8%
All other forms	48%	27.1%	24.8%

*From the Department of Proctology, Miller Clinic, Saint Paul. Thesis presented before the Minnesota Academy of Medicine, Dec. 11, 1929.

In a study of Yeomans complete table of the 347 cases of Dewis and Leichenstern we find 75 per cent of all benign tumors of the intestinal tract were adenomata. Of all the benign growths in the intestinal tract 45.9 per cent, and of the adenomata 63 per cent are found in the rectum, hence well within reach of the examining finger. The moral is obvious.

Fig. 2. Benign adenomatous polyp. Low magnification. Columnar epithelium and large clear glands which are normal in appearance.

Fig. 3. High magnification of specimen shown in Fig. 2.

Age.—As has been said, true multiple polyposis is a disease of childhood and early youth; the acquired polyp one of any age. In 127 cases of multiple polyposis collected in a former paper, the ages were as follows:

TABLE 3

Under 10 years	5
10 to 20 years	23
20 to 30 years	21
30 to 40 years	23
40 to 50 years	11
50 to 60 years	4
60 to 70 years	5
70 to 80 years	1

Of the cases in the above series 65.6 per cent were between the ages of 15 and 35 years. It is of additional significance that of the cases in the series in which the ages were given, over one half had had symptoms for over ten years, so that the age in the series is actually lower than is shown.

Of acquired polyps one writer says "Clinically adenomata occur most frequently in children from 3 to 10 years of age, though they are not unusual in adults." David, writing in Lewis' Surgery states that adenoma of the rectum is frequently found in children from two to five years of age, but is also often observed in adults. In our own series of 25 single polyps the ages ran from three to seventy-one years, distributed as shown in the following table.

TABLE 4

Under 10 years	4
10 to 20 years	0
20 to 30 years	1
30 to 40 years	2
40 to 50 years	3
50 to 60 years	10
60 to 70 years	4
70 to 80 years	1

Our oldest patient was seventy-one years of age, and in the literature are case reports of single adenomas in children of only a few months.

Site.—As has been said 63 per cent of adenomata of the intestinal tract are located in the rectum. These single polypoid tumors may be situated just inside the anal canal, in the ampulla of the rectum, at the recto-sigmoid angle, or in the sigmoid itself. Palpable pedunculated tumors immediately inside the anal orifice are more likely to prove to be hypertrophied anal papillæ or hemorrhoids which have been the seat of inflammatory change. When adenomata develop in this area they sooner or later develop a pedicle of such length that they may protrude from the anus during defecation. A favorite location for

the development of adenomata is the anterior wall of the rectum, proximal to a sharp fold marking the junction of the rectum and sigmoid. In this region a small tumor may escape notice unless the fold is depressed to allow one to see behind it. Carcinoma of the rectum also is often seen in this site, and may quite probably be the result of earlier polyp formation.

Characteristics.—The adenomatous polyp is not in a true sense an adenoma, but merely a polyp covered with more or less normal mucosa. Macroscopically it is bright red, glistening, fairly smooth, but sometimes lobulated like a mulberry, and varies in size from 1 to 2 centimeters in diameter to that of a walnut. Goodsall reports one the size of an orange, and Esmarch one weighing four pounds. It bleeds very easily, and thus has as one of the earliest symptoms the passage of bright blood in the stool. The pedicle may be extremely short and thick, or it may be several inches long, and so slender as to tear off with the slightest traction, liberating the tumor and permitting it to be passed with the stool. Prideaux saw a tumor with a pedicle six inches in length. Microscopically it is seen to spring from the mucosa of the intestine and have a connective tissue stalk covered with glandular epithelium showing a hyperplasia. The stalk usually shows a leukocytic infiltration with the formation of new stroma cells, blood, and lymph vessels. Ewing describes the formation of adenomatous polyps as "inflammatory adenoid hyperplasia."

Malignancy.—In considering the possibility of malignant change in adenomatous tumors of the bowel it is perhaps advisable to regard them as two separate groups, the single or scattered polyps, and the congenital, multiple polyposis. In 36.4 per cent of the collected 127 cases of multiple polyposis there was a known and proven malignancy. Since it was known that an additional thirty-one patients died rather early of cachexia, inanition, or bleeding, it is reasonable to assume that the malignancy index was somewhat higher than the 36.4 per cent that the statistics showed. In Doering's and Soper's series the percentage of malignancy was 43 per cent. Mummery states that almost all recorded cases of multiple polyposis of the colon eventually become malignant.

In the case of the single polyp the question of malignancy is not so easily disposed of owing to the fact that these tumors are usually promptly removed as soon as diagnosed, thus ending once and for all the chance of becoming malignant. In the true multiple type there is ample opportunity to study the changes that take place, and often to observe and study microscopically the transi-

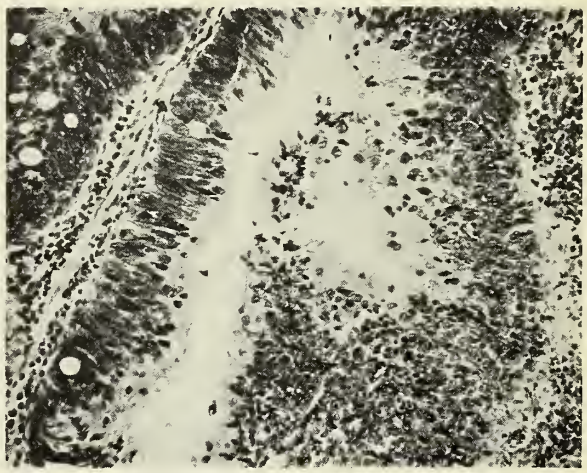

Fig. 4. Adenomatous polyp showing early adeno-carcinoma.

tion. In our own case of multiple polyposis, the rectum and sigmoid were observed frequently through the proctoscope, and from time to time numbers of the larger polyps were removed with the snare, until at the end of two years, cancerous change occurred more or less suddenly at the rectosigmoid junction where the tumors had previously been benign (Figs. 5, 6, 7, 8). From the fact that single benign tumors are frequently seen in young children, one infers that many children have them and go untreated. If these tumors all ultimately become malignant, cancer of the rectum should be more common in early life than is the case, although we have no evidence to prove that these polyps do not remain benign until advanced age and then, only, become cancers. Single polyps are frequently found incidentally during autopsies on persons of advanced age, and have apparently produced no symptoms. Ewing believes that the polyp, which he calls "inflammatory adenoid hyperplasia" demonstrates more clearly than any other process the logical transition from simple inflammatory hyperplasia to carcinoma. Verse thinks that most gastro-intestinal cancers have their origin in adenomata which have arisen from simple inflammatory hyperplasia. In our own series of twenty-five cases, six of the single polyps showed carcinomatous change. It is entirely possible that if every carcinoma of the rectum might be seen

early enough it would prove to be morphologically similar to the six in our series, that is, with a base narrower than the body of the tumor.

Diagnosis.—First, a routine rectal examination should be made of every patient coming for a complete examination, with a thorough investigation of the symptoms of rectal bleeding, instead of a dismissal of it as having its origin in hemorrhoids. In the Massachusetts General Hospital in two years 85 per cent of cases of carcinoma of the rectum coming to operation had been treated for the relief of hemorrhoids within the previous two years. Secondly, rectal examination should be made of all patients with rectal symptoms. By the above should be meant patients with pain about the anus, rectum, sacrum, back of thighs, or left lower abdomen, alterations in the size, shape, consistency, constituents, or color of the stool, deviations from the normal in the sensations accompanying the bowel movements, blood or discharge, constipation coming on suddenly, or diarrhea. Any of these symptoms should certainly be the indication for digital examination, many of them for a proctoscopic examination. As was said earlier, 45 per cent of all benign tumors of the intestinal tract are within reach of the examining finger. On digital examination these tumors are smooth, fairly hard and firm, but not with the firmness of a carcinoma, and usually they may be identified as being definitely pedunculated. Seen through the sigmoidoscope with the patient either on the Haines table or in the knee chest position they present themselves as bright red, glistening round masses, sometimes lobulated like a mulberry, which ooze blood freely when rubbed with an applicator or agitated with the end of the instrument. There is a definite difference in the appearance of a benign polyp from that one which has undergone malignant change which is hard to describe, but which often gives a strong suspicion before a biopsy is made.

Fig. 5. Benign adenomatous polyp removed from patient having multiple polyposis.

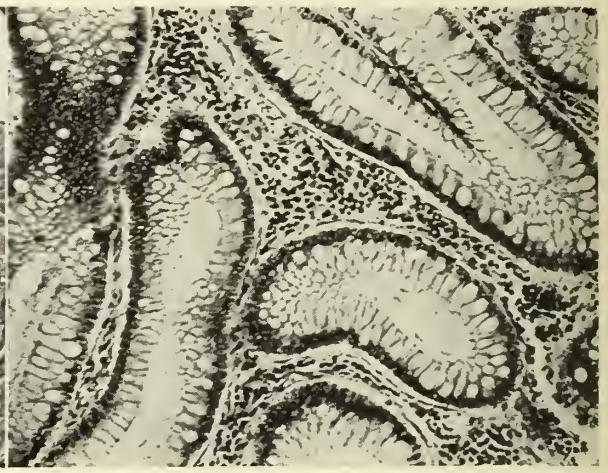

Fig. 6. High magnification of specimen shown in Fig. 5. Glands lined with normal epithelium of the columnar type. Cells filled with mucus.

Symptoms.—The symptoms vary from none at all in the case of early or very small tumors to occasional bleeding, and, depending on the size and location, tenesmus and a sense of incomplete evacuation, to a complete obstruction or intussusception. The symptoms in my twenty-five cases were as follows:

TABLE 5

No symptoms	5
Bleeding only	7
Bleeding and irritation	1
Bleeding and discharge	2
Bleeding and prolapse	4
Prolapse only	1
Bloody diarrhea	2
Sense of incomplete evacuation	1
Pain referred to bladder	1
Obstruction	1

It will be seen that of the twenty-five patients, sixteen had bleeding as one of their symptoms. Regarding blood in the stool as a symptom of carcinoma, Jones has the following to say: "Blood is also present with polyps of the colon or rectum, a condition we have become more and more to believe to be of great importance, of even greater importance than carcinoma itself, for

polyps frequently become carcinoma, and proper treatment before they become malignant means permanent cure." One of our cases had been diagnosed as ulcerative colitis and treated as such for several weeks, while another patient was told she had "intestinal flu." Each had a palpable tumor in reach of the examining finger.

Fig. 7. Section of malignant polyp removed from patient having multiple polyposis. Glands large and irregular.

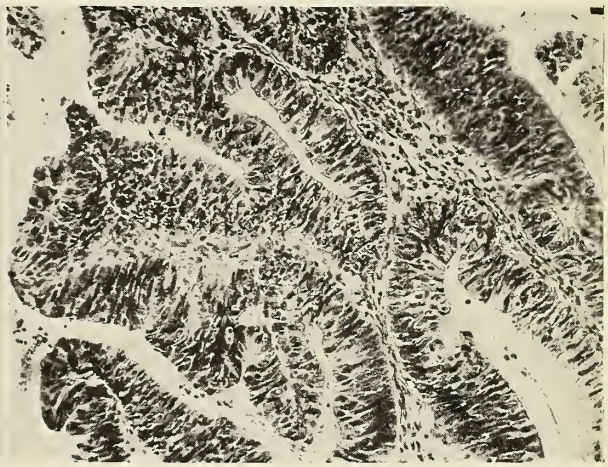

Fig. 8. High magnification of specimen shown in Fig. 7. Giant glands lined with atypical columnar epithelium.

Treatment.—Adenomatous polyps should be considered as distinctly premalignant growths and as such should be eradicated when seen. The low-lying tumors may be prolapsed after the sphincter has been relaxed with novocaine, and, after the pedicle has been ligated, the tumor may be removed. Those which are too high to draw through the anal orifice may be removed with the snare through the proctoscope. There are one or two precautions to be observed in this procedure. In the case of a tumor situated above the peritoneal reflection, it is readily seen that too much tissue may be included in the snare so that when it is drawn taut, an opening into the peritoneal cavity may result. Care should be taken to grasp only the pedicle. Secondly, there may be rather troublesome bleeding if a cold snare is used, and the growth removed too quickly. If one uses such a snare the wire should be drawn up very slowly, allowing three or four minutes for the pedicle to be pinched off, in order that the vessels may become closed. The base may be touched with an applicator dipped in some cauterant to insure its remaining dry. In one of our cases a polyp 2 centimeters in diameter was snared from the posterior wall at the rectosigmoid junction. The stump was observed for a time until it was felt that all bleeding had stopped, when the patient was allowed to go home. During the following eight hours he was compelled to empty his rectum four times, each movement consisting of large clots. After the fourth movement he reported his condition and an investigation was made. On cleaning the clots from the rectum a steady drip of blood was seen coming from the stump of the pedicle, and it was only after fulguration that the bleeding ceased. Since that occurrence I have used a high frequency snare and have had no repetition of that embarrassing complication. In my cases the malignant polyps were snared and the bases thoroughly cauterized or fulgurated. In one case radium was used after fulguration. One case went elsewhere for treatment and had a radical excision of the rectum with a permanent colostomy.

Fig. 9. Adenomatous polyp. Inflammatory type.

Of the six cases with carcinomatous change,

one patient died five days after a colostomy for obstruction due to a large carcinoma above his smaller polyp, the other five are alive, at various periods of from three years to four months after removal of the polyps. One of the cases of benign adenoma died later of carcinoma of the bladder, and another of an obstructing carcinoma above his benign polyp. The remainder are alive and well.

THE FEMALE SEX HORMONE

At the thirteenth International Congress of Physiology in Boston, held in August, 1929, E. A. Doisy announced for the first time the isolation of the female sex hormone in crystalline form. Subsequently, A. Butenandt announced that he, too, had isolated the hormone of the female sex glands in chemically pure crystallized form. In an article describing the product, Butenandt completely ignores the Doisy announcement. Butenandt points out that the substance is free from nitrogen and sulphur, and that it has no connection with protein substances and carbohydrates. In his opinion, a chemical analysis may make it possible to produce the hormone synthetically. As might have been anticipated, the German investigator promptly conferred on his product a trade name controlled through a German manufacturer. Doisy, aided by the Council on Pharmacy and Chemistry, will no doubt choose a scientific name suitable to the nature of the product and to American conditions. (Jour. A. M. A., February 1, 1930, p. 341.)

THE COMMITTEE ON FOODS

More than a hundred products, representing the products of numerous manufacturers, have been submitted to the committee, in addition to several national advertising campaigns by coöperative marketing organizations. This coöperation is welcomed by the committee but obviously has thrown a great burden of work on the committee at the start. Manufacturers have greeted with acclaim the permission to use on packages and in advertising the seal of the committee. Whereas less food is eaten, so far as concerns caloric or energy value, foods have been greatly modified to improve palatability and to provide what are recognized as necessary ingredients in the form of vitamins and mineral salts. It is the hope of the committee that its efforts will give stability to a rapidly growing industry and prevent the sinking of the modern food market in a morass of hokum such as engulfed the drug industry in its developing stages. (Jour. A. M. A., February 8, 1930, p. 415.)

POSTOPERATIVE HYPOTHYROIDISM*

M. G. Gillespie, M.D.
Duluth, Minnesota

THE condition of lowered metabolism, or myxedema, following surgical treatment of goiter, although long recognized, has received comparatively less attention than its adverse condition, hyperthyroidism. This is rather surprising when one considers how partial thyroidectomy for goiter has been popularized, especially during the last quarter of a century.

This negligence in the study of hypothyroidism can probably be best explained by the fact that immediate operative results in goiter as a rule are so startling that they are deceiving. A patient suffering from hyperthyroidism will present following operation such an immediate and striking improvement that the surgeon is thrown off guard, and the patient is dismissed as recovered, when weeks or months later a condition of hypothyroidism will supervene which is so insidious in its onset that even the patient does not recognize its beginning, but considers his or her condition as a matter of course, and, with few exceptions, will not seek further attention.

It was the recognition of an occasional case of an immediate temporary hypothyroidism and an occasional case of myxedema, discovered in a partially thyroidectomized individual weeks or months later, that led us to institute a follow-up study of metabolism in all cases of partial thyroidectomy.

The material for this paper consists of metabolism studies in a group of 209 patients who had been operated on for goiter from one to seven years previously. In this group of 209 cases there were fourteen patients with a definite hypothyroidism, in whom the diagnosis had been either suspected or definitely proven and had been under treatment, some haphazardly, others rigorously, with thyroid preparations over a period of months or years.

These patients came in for metabolism study in response to a questionnaire. Recognizing the fallacies that a stereotyped questionnaire may lead to, it was considered wise not to adduce too many conclusions, and therefore the greater part of this paper will be confined to an analysis of the metabolic study.

Since the middle of the Nineteenth Century, when Reverdin,[1] and at about the same time Kocher, first recognized postoperative myxedema, there had been no extensive attempts to follow up goiter cases until the introduction of basal metabolism. Among the earlier contributors of case reports on the continent were von Eiselsberg, Möbus,[2] Munk,[3] and Roux.[4] Bonilla and Blanco Soler[5] state that postoperative myxedema is rare, and that the low percentage of postoperative myxedema is due to the existence of accessory thyroid glands. Seulberger[6] reported a case of postoperative myxedema and tetany in a patient who had a typical Graves' disease with operative removal. Nobel[7] reported a case of postoperative myxedema in a child thirteen years of age.

Since the introduction of basal metabolism, systematic study and follow-up systems have been attempted, not only in goiter series but also in so-called medical hypothyroidism. King[8] has reported thirty-six cases of hypothyroidism occurring in hospital patients, from a group of 200 cases, only three of which followed thyroidectomy. Jordan[9] has reported eighteen cases in which the basal metabolic rate ranged from minus 16 to minus 27; five only (.9 per cent) had clinical myxedema necessitating treatment. Smith, Clute and Strieder[10] reported an incidence of postoperative myxedema of 15 per cent in 100 patients who had been followed for one year after operation. Thompson and Thompson[11] have made an exhaustive study of metabolism, and report in a group of permanent low metabolism, with permanent myxedema, an occurrence of 2 per cent in 465 cases, 130 of which had been treated by *x*-ray alone, and in this group the incidence of myxedema was 4 per cent.

For the diagnosis of postoperative myxedema, I consider essential a low metabolic rate following an operative attack upon the thyroid, edema and a definite improvement in general and an increase of the basal metabolic rate to normal, under thyroid medication.

*From the Duluth Clinic, Duluth, Minnesota. Presented at the annual meeting of the Northern Minnesota Medical Association, Bemidji, Minnesota, September 3, 1929.

In this group of 209 cases, there were forty-five with basal metabolic rates of minus 10 and lower. I have selected those with rates of minus 10 and lower because I soon learned that there were no cases of definite hypothyroidism with basal metabolic rates above minus 10—in fact, as a general rule, the lower the metabolism, the more definite and striking the hypothyroidism. There were some cases where the rates fell between 0 and minus 10, and because of rather indefinite complaints they were put on desiccated thyroid, and were kept under observation and their rates rechecked; but none of them experienced any improvement when their metabolism was elevated.

In this large group of forty-five cases with metabolic rates less than minus 10, there were two natural divisions: the first, those with a definite hypothyroidism, of which there were twenty-five, with basal metabolic rates ranging from minus 14 to minus 44, and a second group, which I wish to term low metabolism without myxedema, with rates from minus 10 to minus 15, of which there were twenty. In this second group there were fourteen females and six males; the ages ranged from 25 to 62 years. Eleven, or approximately one-half, followed subtotal thyroidectomy for exophthalmic goiter; six followed resection for non-toxic adenomata; and three followed subtotal thyroidectomy for what we wish to term "borderline" cases. In seven cases, or approximately one-third of the group, there were no complaints whatsoever. Seven, or another third, had a definite neurosis, and this group included all the borderline cases. In four of the last group there was some suggestive improvement, although there was still a persistence of neurotic complaints.

Of the twenty-five cases which fell into the definite group of hypothyroidism, the basal metabolism, as mentioned before, ranged from minus 14 to minus 44. In this group there were twenty-four females and one male; the ages ranged from 20 to 63 years. Nineteen, or approximately four-fifths of the cases, followed subtotal thyroidectomy for exophthalmic goiter. There were three each following operation for non-toxic adenoma and toxic adenoma. Five cases of this group had had multiple operations upon the thyroid.

The diagnosis of many of these cases was obvious on inspection. It will be remembered that in fourteen of the group of twenty-five cases the diagnosis had either been suspected or definitely proven months or years before, and have been under observation innumerable times since operation.

Weakness and fatigue were the outstanding subjective complaints. The others, in the order of their importance, were dyspnea, palpitation, a feeling of being too cold, and a dry skin.

Objectively, the findings varied somewhat. It will be remembered that several of the patients, when they came in for this metabolic study, were already taking their daily dose of thyroid, and in these, at that time, there was not much deviation from the normal, although I recall vividly that in some of these cases, following thyroidectomy, there was the classical picture of myxedema, with edema, loss of hair, dry coarse skin, and mental and physical sluggishness.

In one-half the cases, and this is true also of the group of low metabolism without myxedema, there was no gain in weight. The remaining half showed an average gain of approximately twenty pounds.

The outstanding objective finding was edema of the face and extremities. This varied a good deal with the degree of myxedema, but in a few of the cases it was very marked. Other outstanding objective findings included a dry scaling skin. In some of the more marked cases the skin had the appearance of being tough and inelastic. Another striking change was the loss of hair, especially from the eyebrows, and a change in the texture of the hair from a fine to a coarse type. Another change was a characteristic physical and mental sluggishness. Many of these people found great difficulty in arousing themselves in the morning and many of them again complained bitterly of mental apparitions.

In only four cases of this group was the blood pressure elevated, and this was explained on the basis of a concomitant essential hypertension as these patients were all over fifty years of age.

In only six cases was there a definite anemia.

In the treatment of these cases an attempt was made to bring the metabolism up to a normal level and to maintain it at that level by frequent repetition of the basal rate reading. It will be remembered again that fourteen patients had been taking thyroid gland, either as the desiccated whole gland or the extract or as thyroxin, intermittently for months or years. Most of

them had learned to regulate their dosage by experience. It was found that there was a definite improvement both subjectively and objectively in every case.

Summary.—A group of 209 cases in which subtotal thyroidectomy for goiter had been performed from one to seven years previously is reported. Of this number, twenty-five, or approximately 8 per cent, had a definite hypothyroidism or myxedema. In this group the basal metabolism ranged from minus 15 to minus 44.

Another group of twenty cases, with basal metabolic rates ranging from minus 10 to minus 15, was not materially benefited by thyroid medication.

The outstanding subjective complaints were weakness and fatigue.

Objectively, edema and a metabolic rate of minus 15 or more were the significant findings.

Conclusions.—1. Postoperative goiter cases merit more careful study and more rigorous follow-up, especially in regard to their metabolism.

2. A certain percentage, in this series approximately 8 per cent, show a definite hypothyroidism after subtotal thyroidectomy.

3. Proper thyroid medication will improve every case of definite hypothyroidism.

EARLY OR LATE OPERATIVE TREATMENT IN COMPLICATIONS OF ACUTE OTITIS MEDIA*

John J. Hochfilzer, M.D.
Saint Paul

BEFORE I go into the selected theme, I want to say a few words about the etiological, anatomical, and pathological processes, and the clinical symptoms in acute otitis media.

1. In regard to the etiology of acute otitis media: There are just as many causes for acute purulent otitis media as there are diseases in human beings. Each one of them can be the originating factor. To begin with, all infectious diseases like scarlet fever, la grippe, and many others, can cause otitis media. In these cases the otitis media is a part of the generalized morbidity, but in all cases of otitis media one is able to find a general or local disease as the etiological factor. But, whatever the original cause may have been, one thing is certain, that it is an infection of the tympanic cavity by certain organisms. From a scientific standpoint, it has not yet been proved that the tympanic cavity is free from organisms, but from a clinical point of view we can call the tympanic cavity sterile. In the diseased tympanic cavity we nearly always find bacteria. Its four main offenders are: *the streptococcus pyogeneous, streptococcus mucosus, diplobacillus lanceolatus,* and the *staphylococcus aureus.*

Naturally many other microörganisms are found in acute otitis media besides those just mentioned, especially those which cause the different infectious diseases, like diphtheria, typhoid fever, and so on.

2. The mode of infection: In 90 per cent of all cases the infection of the tympanic cavity is caused by the way of the Eustachian tube and usually along the surface of its epithelium. The hematogenous source of infection is much more rare.

3. Predisposing causes for infection: These for instance may be a lymphatic habitus of children, emaciation, local obstruction of the Eustachian tube from hypertrophic tonsils and adenoids, or congenital defects in the epipharyngeal area.

4. Pathologic anatomic changes of the mucous membrane of the tympanic cavity: At first the mucous membrane is infiltrated, then edema follows, later the stage of exudation, and if the process does not come to a standstill, at that stage, the bony structure will be also involved, and we have a regular local osteomyelitis.

5. The clinical symptoms: The first clinical subjective symptom of a beginning otitis media is earache, which is one of the most severe pains human beings are liable to suffer, as everybody who ever had earache can verify. Often with it comes tinnitus aurii of a pulsating character. A diminution of hearing accompanies these symptoms, but it is not very noticeable in the beginning. Some patients also complain of dizziness. The local retroauricular glands are swollen, and quite often one finds tenderness over the mastoid process, even in the beginning stage. General symptoms of otitis media are: chills, fever, and nausea.

6. Course and prognosis: Sequela: (a) a slow recession of all symptoms without perforation of the ear drum by the accumulated exudate. (b) Perforation of the ear drum by the purulent exudate. (c) The acute otitis media becomes chronic. (d) Manifestations of complications, the beginning of which is nearly always some bone involvement.

7. Treatment: (a) General therapeutic measures, like rest in bed, aspirin, and laxatives. (b) Local treatment: Phenol glycerin or cocain drops, hot applications and finally paracentesis. (c) After treatment: The ear canal is kept as clean as possible. Some use only dry cotton; some irrigate the canal with boric solution or hydrogen peroxide.

After this brief description of the usual course of acute otitis media we come to the question, what are the indications for operative procedure in acute otitis media? Unfortunately, medical science is not far enough advanced to prevent complications by conservative treatment in every case of otitis media. On the contrary, our remedies for the treatment of acute otitis media are

*Read before the Ramsey County Medical Society, Saint Paul, Minn., November, 1929 .

about the same as they have been for the past twenty-five years, and they are mostly symptomatic. A famous otologist once said, "Our medical remedies in otitis media are so few, that we can write them on one finger nail." But we can be of more help to those otitis media patients in whom complications have set in. Here, surgery has its place and cases which were hopeless before the surgical era, can be saved nowadays, thanks to the advancement of surgery in this special field. A paracentesis performed at the right time is just as much a life saving operation as an appendectomy in acute appendicitis. Therefore our ambition should be to increase our knowledge steadily regarding the indications for operative procedure in acute otitis media, which are not so well established, as for instance, the indications for surgery in acute appendicitis.

Especially in the last few years there has been a great deal of difference of opinion among otologists as to the right time for surgical procedure in complications of acute otitis media. Some prefer to operate as soon as the slightest symptom of a possible complication appears. Others wait and treat such cases conservatively and more observingly. The first group operates every otitis media, which has not stopped draining after two weeks of conservative treatment, the later postpones surgery as long as possible, until certain symptoms of complications have manifested themselves, asserting that such a conservative attitude does not endanger the life of the patient more than many unnecessary operations performed by those who follow the radical method.

The indications for mastoidectomy as generally established seem to be:

1. Objective symptoms of a destructive process of the bony structure, that is, infiltration or abscess formation in the mastoid process or its surroundings, sagging of the posterior wall of the ear canal, or symptoms of a fistula of the inner ear.

2. Where the discharge from the ear constantly is very profuse or even increases in spite of several weeks of conservative treatments.

3. When repeated paracentesis has been unsuccessful.

4. Persistent increased temperature. Besides these subjective and objective signs of bone destruction are others, more generalized symptoms, which indicate surgery in otitis media, for instance, loss of weight and poor appetite in the course of an otitis media, or meningeal irritation and a pathological spinal fluid indicating a threatening intra-cranial complication. The conservative group among the otologists followed the rule, never to operate before three weeks have elapsed since the onset of the otitis media. The rule may be right when the otitis media takes the usual course as described in text books. That is, during the first week is the stage of pain with a constant fever curve. The second stage is that of sero-purulent secretion, and decrease in the fever. The third stage is accompanied by purulent secretion, and an increase of temperature.

Quite often one notices even in the first stage a tenderness over the mastoid process upon pressure, known as matoidismus. This does not indicate that the bony structure must be effected; but a tenderness over the mastoid process at the end of the second or at the beginning of the third week means a complication in the course of otitis media.

But only a small percentage of otitis media cases take such a typical course. One often observes cases which do not fit in any of the previous mentioned stages. They are the ones which require painstaking examination and observation to enable us to decide whether surgical or conservative treatment should be adopted.

I shall mention here a few cases which show such an abnormal course, and so give quite a different indication for the operation. At the clinic of Professor Neumann[1] in Vienna, a series of cases were reported in which the otitis media, following a grippe epidemic, took a very foudroyant course. In these cases, two days after the beginning of earache, signs of meningeal irritation were manifest, like nausea, dizziness, pain in the occiput. In spite of immediate paracentesis no improvement took place. The spinal fluid was cloudy, showing an increased cell count, polymorphoneuclear leucocytes predominating. On account of these findings mastoidectomy was performed, very little pus being found in the pneumatic cells and antrum. A couple of days later the patient died. The autopsy showed a localized meningitis at the site of the affected ear. Similar cases were described recently by Otto Mayer.[2] Among these cases is one especially interesting, because it came under observation of an otologist from the very beginning of the morbidity.

A fourteen year old boy complained of earache. The otologist was consulted immediately. He made a diagnosis of beginning otitis media. The temperature was

100 degrees followed by a rise in temperature to 101 the same evening. A paracentesis was done. Two days later nystagmus and dizziness set in, with diminution of the hearing, so that a whispering was heard at a distance of two meters only. Kernig's sign was positive, and the spinal fluid cloudy. Thereupon mastoidectomy was done. In the mastoid process large cells were found, but no pus, and in the antrum a hemorrhagic exudate (streptococcus). Death followed fourteen hours after the operation.

Another case which came under my observation shows also how fast complications can develop.

This patient had terrific earache ten days after a normal childbirth. She was still in the hospital and therefore was also observed from the beginning. Examination a few hours after the onset showed a much inflamed ear drum with bleb formation. A paracentesis was done, hemorrhagic exudate escaped, and the patient obtained temporary relief. Two days later the temperature rose to 102, the pain increased, and there was tenderness over the mastoid process. The discharge from the paracentesis opening being very scant, a second paracentesis was done, and again a temporary relief followed. But the temperature remained high on the following day, the tenderness over the mastoid process was more marked, and at the tip of it a swollen area was noted, which indicated a probable perforation through the bone. On account of this, mastoidectomy was done. Pus was found in all the pneumatic cavities, especially at the tip, but no perforation. The sinus was free. Two days after the operation the temperature was close to normal, and the patient made an uneventful recovery.

In this case there was a fully developed mastoiditis on the fifth day after the onset. Usually this kind of a complication is hardly to be expected before the second or third week after the onset. The childbirth may have played a part in this case. The resistance was lowered and therefore the local infection of the ear could spread much quicker in the neighborhood and developed a complication in such a short time.

The opposite course in otitis media, I observed just recently in a ten year old boy.

This patient had repeated attacks of earache for a week before I saw him. Upon examination I found an inflamed ear drum with bleb formation, and besides a swelling in the temporal region extending over the zygomatic process to the external canthus, moderate tenderness, and a temperature of 100 degrees. The mastoid process itself was not tender, so we had an acute otitis media with the onset of complications in the bony structure. Here the pneumatic cells were abnormally located in the temporal region, and there the bone involvement originated. Paracentesis was done immediately and a considerable amount of purulent fluid escaped. Hospitalization was advised for further observation. The pains decreased, but the swelling over the zygomatic process increased, involving the whole temporal region and right eye, which showed a marked edema of the lid. The temperature was stationary. Operation seemed to be unavoidable, and was recommended by a consultant; but further observation was justified, because we know that such cases seldom cause any intracranial complications like sinus thrombosis or a brain abscess. The next few days showed marked improvement in the condition of the ear drum, the inflammatory process ceased, the discharge decreased, the temperature became normal and there was less pain over the swollen area. The patient made an uneventful recovery from then on.

In this case, according to rules generally applied, surgical intervention would have been indicated, but close clinical observation saved the patient from it.

Paul Hopkins[4] from St. Mary Victoria Hospital in Berlin, recently published statistics of 303 cases of acute otitis media which had been operated. His statistics are based from the onset to the time of operation. He divided them into three groups according to the time of operation, whether during the first, or second, or third week (or later) following the onset of symptoms. In his experience it did not make a great deal of difference at what stage these patients were operated upon, as far as probable complications, like sinus thrombosis, brain abscess, meningitis, and mortality were concerned. On the contrary he found a greater mortality in patients who were operated during the first week following the onset. The reason for this he believes, is the virulence of the infection, and a low resistance of the individual in the first week.

It was thought that roentgenology would be of a great help in determining the right time for surgical intervention in acute otitis media. But our expectations were not quite fulfilled. For instance in children, radiology is of very little help, because we find not infrequently in the first stage some haziness in and density of the mastoid process, which may lead to false interpretation and in turn to an unnecessary operation. In children apparently every otitis media shows some effect on the mastoid process, but in nearly 90 per cent of these cases all these symptoms subside without any further complications.

In adults, the radiogram shows us the distribution of the air cells in the mastoid process. Pathologic conditions in the mastoid may cause bony destruction which would be indicated in the radiogram by increase in density. But in normal cases there are variations in the air content of the mastoid process, which is reflected in the radio-

gram, without meaning that pathology is present. In advanced cases of mastoiditis, the radiogram gives us full information about bone destruction, confluence of mastoid cells and formation of abscess cavities. But in this stage the clinical symptoms are usually so outspoken that a correct diagnosis can be made without a radiogram, and the proper treatment instituted.

In spite of all the technical help which is at our disposal nowadays, we still have to rely on the clinical findings and personal experience, more than on anything else, to determine when operative treatment is indicated in complications of acute otitis media, and so we may draw the following conclusions:

1. It is impossible to decide at the onset, whether a case of acute otitis media belongs to the group where early surgical intervention is necessary, or to a group where conservative treatment has its place.

2. Painstaking clinical observation only can decide the right moment for operative procedure.

3. Complications like meningitis, sinus thrombosis, brain abscess, can occur at any stage in the course of otitis media.

4. The end results of the treatment of acute otitis media do not vary a great deal, whether the case has been operated in the early or late stage. Apparently the more conservative method has produced better results than the more radical one.

VIGANTOL NOT ACCEPTABLE FOR N. N. R.

When reports of experimental clinical studies made it apparent that irradiated ergosterol preparations would be offered for therapeutic use, the Council on Pharmacy and Chemistry undertook to select a name for this vitamin D bearing product. The Council did this so that products of this kind might be marketed under a single name and thus the confusion avoided which inevitably results when the same product is marketed under a multiplicity of names. The Council adopted "Viosterol" as the New and Non-official Remedies name for irradiated ergosterol and the name "Viosterol in oil 100 D" to designate a preparation containing the substance dissolved in oil and having one hundred times the vitamin D potency of a standard cod liver oil. Four firms have made their products acceptable under the Council name for inclusion in New and Nonofficial Remedies. The Winthrop Chemical Co. is offering to physicians of the United States a brand of viosterol in oil 100 D under the proprietary name "Vigantol." The Council declared "Vigantol" unacceptable for New and Non-official Remedies because the application of a proprietary name to a preparation of irradiated ergosterol is contrary to the best interest of the medical profession and of the public. (Jour. A. M. A., February 8, 1930, p. 410.)

HERNIAL (INYECCIONES PROLIFERANTES OBTURADORAS DEL DR. E. PINA MESTRE) NOT ACCEPTABLE FOR N. N. R.

The Council on Pharmacy and Chemistry reports that the product "Inyecciones Proliferantes Obturadoras," stated to be manufactured by Dr. E. Pina Mestre of Barcelona, Spain, was presented to the Council for consideration under the name "Hernial" by the Vincent Ruiz Co., New York. According to the information submitted by this firm, "Each ampule contains approximately 98% of alcohol, and the balance consists of the following ingredients expressed in percentages: 25% Krameria, 16% Katechu, 15% Rosa Canina, 15% Rosa Centifolia, 14% Vaccinium Myrtillus, 15% Monesia." The preparation is proposed for use by injection in the treatment of hernia. The Council declared Hernial (Inyecciones Proliferantes Obturadoras del Dr. E. Pina Mestre) unacceptable for New and Non-official Remedies because it is an unscientific, indefinite and complex mixture of astringent drugs proposed for use in the treatment of hernia, for which unwarranted claims are advanced and the use of which is not warranted by the available evidence but, on the contrary, is considered to be dangerous. (Jour. A. M. A., February 1, 1930, p. 339).

PROBLEMS IN PLASTIC SURGERY OF THE NOSE*

Gordon B. New, M.D.
Rochester, Minnesota

PATIENTS who present themselves for the correction of nasal deformities are usually of three types: (1) those with some minor deformity, the result of an injury, such as a humped or crooked nose, or a nose that it too long, too short or too broad; (2) those with a major defect such as a marked saddle-back deformity, or loss of the ala or the greater part of the nose from syphilis, or the result of malignant destruction, and (3) those with an imaginary deformity which to them is marked, and about which they are extremely sensitive. Patients in the third group are usually psycho-neurotic, and require careful treatment. I am reporting here six cases, that are illustrative of some of the problems in the surgical treatment of nasal deformities.

SADDLE-BACK NASAL DEFORMITY

Case 1.—A girl, aged eighteen years, came to The Mayo Clinic October 21, 1929, for correction of a saddle-back nasal deformity. Her nose had been injured ten years previously, and an abscess had formed and required drainage. The saddle-back deformity had resulted. Treatment had not been given.

Examination revealed the tip of the nose to be turned up (Fig. 1). The septum was not markedly deformed. The Wassermann reaction of the blood was negative. Operation was performed, October 24, 1929, under intratracheal ether anesthesia, at which time a full thickness of the cartilage of the right eighth rib was removed. The wound of the thorax was closed in the usual manner with catgut, silkworm and dermal sutures, leaving a silkworm drain for a few days to take care of any oozing that might occur. A pressure dressing with adhesive plaster was used over the lower part of the thorax. The skin and subcutaneous tissue over the tip and the bridge of the nose up to the glabella was well freed by means of dissecting scissors, through a small incision just below the tip of the nose. After the cartilage had been shaped to conform to the deformity, it was inserted through the incision. The wound in the nose was closed with dermal sutures. A splint or pressure dressing was not applied. Figure 2 shows the postoperative result.

Case 2.—A woman, aged forty-six years, came to the clinic, June 12, 1928. One year previously the patient had been injured in an automobile accident, receiving a fracture of the base of the skull and of the lower jaw, a compound fracture of the nose, and several lacerations of the face. Immediate emergency treatment had been given, but nothing further had been done for the nose. The patient desired a plastic operation to correct the external nasal deformity as well as the difficulty in breathing through the nose.

Examination revealed a posttraumatic deformity of the nose with a marked saddle-backed nasal deformity (Fig. 3). There was displacement of the nasal bones to the right and considerable thickening of the lower part of the bones on the right side. A scar was present across the nose, extending from below the left eye across the bridge to the right cheek. There was complete atresia of the right nostril, partial atresia of the left nostril and complete traumatic atresia of the left external auditory canal. General examination disclosed chronic cholecystitis with stones, and adenomatous goiter without hypertension.

The patient was operated on June 16, 1928, at which time both nasal bones were refractured and reset in position. An opening was made into both nostrils and rubber tubes were inserted in order to maintain the openings. A copper splint was applied, with a dressing of adhesive plaster. The bones healed nicely in their new position. On July 10, the atresia of the left external auditory canal was freed and the scar was dissected out as thoroughly as possible. A number 18 French catheter was inserted into the canal. The patient was dismissed three weeks later with the rubber tubes still in position in the nostrils and the canal of the ear to be replaced and taken care of by her home physician.

The patient returned, January 3, 1929, with an excellent result of the external nasal deformity. She was still wearing the tubes in the nose, but she had practically a normal ear canal.

July 10, 1929, the patient returned again for correction of the external nasal deformity. By means of intratracheal gas anesthesia a large piece of cartilage was removed from the right eighth rib. The patient was very fat, which made the removal more difficult than usual. The cartilage was inserted to elevate the saddle-back nasal deformity through a small incision just below the tip of the nose. Figure 4 shows the postoperative result.

Comment.—Case 1 represents the deformity that occurs following injury before the nose was fully developed, and case 2 represents the deformity following injury after the nose has developed. Traumatic atresia of the nostrils and the external canal of the ear are best taken care of by means of rubber tubes. The size of the tubes may be increased from time to time, until the nostril or external canal is as large as is thought advisable. It is usually necessary to leave the rubber tubes in place for at least six months. Then the tube should be left out for

*From the Section on Laryngology, Oral and Plastic Surgery, The Mayo Clinic, Rochester, Minnesota. Submitted for publication December 26, 1929.

short periods and replaced if there is any tendency for the opening to contract, the period of time the tube is left out being gradually lengthened. Although a full-thickness skin graft or a Thiersch graft may be used on the rubber tubes in the nose, the tube alone gives satisfactory results.

1 2

Fig. 1 (Case 1). Traumatic saddle-back nasal deformity, the result of an injury when a child; the turned-up nose is shown.

Fig. 2 (Case 1). Postoperative appearance after cartilage implant.

Cartilage or cartilage with bone, as advocated by Carter, is the most satisfactory material for the correction of saddle-back deformity. It is always advisable to take a full thickness of the rib, no matter how small the deformity. Small portions elevated from one side of the rib usually are of little value. The perichondrium is always removed, except in cases in which it is left in place in order to give that portion of the implant a curve or concavity. In case 1, the turned-up nose was corrected by lengthening it with cartilage.

The most important part in the correction of this type of deformity is the fitting of the cartilage to the remaining portion of the nasal bones. Accurate observation of the outline and slope of the nasal bone where the cartilage implant will approximate is necessary. Although various sites may be selected for an incision, the small incision below the tip of the nose, similar in shape to a flying bird, seems to be the most satisfactory. These patients experience very little local reaction. They are usually uncomfortable and in bed for a day or so on account of the removal of the rib. The sutures in the nose are removed on the third or fourth day.

SCOLIOTIC OR HUMPED NOSE

Case 3.—A woman, aged twenty-eight years, came to the clinic, September 17, 1928, for the correction of a deformity of the nose which had been present since birth. Originally her nose had been large and broad with a hump in the bony bridge and a long tip. Six years previously her nose had been injured in a basketball game, a minor fracture being sustained. This did not seem to change the deformity. The patient was anxious for improvement.

3 4

Fig. 3 (Case 2). Traumatic nasal deformity with complete atresia of both nostrils and displacement of the nasal bones, corrected by means of refracturing the nasal bones, placing of rubber tubes in the nostrils, and later, a cartilage implant.

Fig. 4 (Case 2). Postoperative appearance.

Figure 5 shows the deformity at the time of examination. Operation was performed, September 21, 1928, under local anesthesia with 0.5 per cent procaine. An incision was made, inside the vestibule of the nose on both sides, and the entire subcutaneous tissue and skin was freed over the dorsum and lateral portions of the nose. The hump was removed by means of a heavy bone forcep. The nose was shortened and the tip was raised by removing a V-shaped piece from the septum and lateral alar cartilages, closing the incisions with mattress silk sutures. Figure 6 shows the postoperative result.

Case 4.—A man, aged twenty-nine years, came to the clinic, October 1, 1924, for the removal of a nasal hump. The patient had fallen and struck his nose at the age of three years, and a thickening formed at this point which gradually increased. Two weeks previous to examination, the patient was struck on the nose with a croquet ball, which apparently accentuated the deformity.

Examination revealed a marked hump extending from the glabella down to about 0.5 cm. above the tip of the nose (Fig. 7). The nose was markedly thickened laterally. A deflected septum completely obstructed the right side of the nose.

October 4, 1924, submucous resection was done under local infiltration and block anesthesia. October 13, the tissues were freed over the bridge of the nose, and the

bony hump, which stood up 1.5 cm. and extended from the glabella down to just above the tip, was removed by means of bone forceps. Figure 8 shows the postoperative result.

Comment.—The correction of minor deformities, as shown in these two cases, has a definite place in plastic surgery of the nose. In case 3, although the deformity was not marked, the patient was sensible and felt that the correction of this slight deformity was well worth while. In these cases it is well for the patient to understand just how much to expect. It is of little use to tell the patient to go home and forget the deformity, as most of these patients know just what they want done, and are perfectly satisfied if the work is done correctly. In Case 4, the deformity was more obvious, and the correction put the patient in a much better position to earn a living. The use of rasps in these cases frequently stimulates overgrowth of bone which appears secondarily, so that removal of the humps of bone with saws or bone forceps is the preferable method.

SYPHILITIC NASAL DEFORMITIES

Case 5.—A girl, aged seventeen years, came to the clinic originally, November 29, 1921, on account of hereditary syphilis. At that time there was complete loss of the columella and the bony and cartilagenous septum. She had been given antisyphilitic treatment for a long time, until it was thought advisable to attempt to correct the deformity.

At the time of examination, March 16, 1925, there was a saucer-shaped deformity of the face with flattening of the nose and upper lip (Fig. 9). There was loss of the columella as well as of the lining of the tip and both alæ. The cartilagenous and bony septum was entirely gone.

Several plastic operations were done in an attempt to correct the deformity in a conservative way, with little real benefit. It was decided to raise a flap from the forehead and then to bring it down, turning in the lower portion on itself in order to form the lost portion of the lower third of the nose and make a columella. The first operation to elevate the flap from the forehead, with a pedicle in the region of the glabella and the distal end running into the left forehead, was done February 4, 1929. After two weeks the flap was brought down into position, after the skin had been excised over the remaining portion of the tip and ala. The flap was turned in on itself to form the columella and ala on both sides of the lost tip. Rubber tubes were inserted in the nostrils to maintain the vestibule, and mattress sutures were carried through the skin to hold the nose and ala in position. A full-thickness skin graft replaced the distal portion of the flap on the forehead. After the flap had been in position about two weeks, it was partially cut across, and a few days later completely cut across and sutured back to the forehead. The suturing of the upper part of the flap on the nose was completed. Figure 10 (November 19) shows the postoperative result with the columella and nasal vestibules.

Comment.—Syphilitic deformities may be the result of congenital or acquired syphilis. In congenital syphilis the saucer-shaped face, with loss of the lining of the nose and the columella, is the most common deformity. The saddle-back deformity in these cases may be corrected in the usual manner, by means of a cartilage implant, but the saucer-shaped face usually requires the bringing forward of the nose and the upper lip

by means of an operation suggested by Blair. Replacement of the columella may be done by elevating a flap from the upper lip with a pedicle at its upper portion, and after the under surface is lined with a full-thickness graft, it may be brought up in position and sutured to the posterior surface of the tip of the nose. The wound

9 10

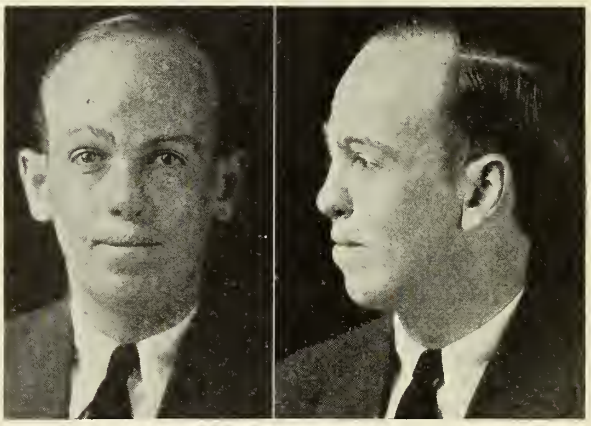
Fig. 9 (Case 5). Syphilitic nasal deformity; loss of the intranasal tissue and the columella.
Fig. 10 (Case 5). Reconstructed skin and lining of the nose forming a columella with a flap from the forehead.

in the lip is closed primarily. The loss of the entire lining of the nose in adults may be replaced by the use of dental compound covered with a Thiersch or full-thickness skin graft attached by means of a splint to the upper teeth, first freeing the entire skin over the nose and bringing it forward. This method was suggested by Gillies. The use of a full-thickness skin graft, however, gives a more dependable lining than the Thiersch graft. In case 5 the loss of the lower third of the nose, with the lining in the columella, was corrected by means of a flap from the forehead, following the method of Nélaton.

POSTOPERATIVE LOSS OF A PORTION OF THE NOSE

Case 6.—A man, aged thirty years, came to the clinic, February 13, 1928, because of a lesion on the dorsum of the nose, which had been present for five years and had been treated extensively with roentgen rays over a period of two years. Two roentgen-ray burns had developed on the dorsum of the nose and on the left ala. The roentgen-ray treatments were continued, alternated with different types of ointments. Following this he was treated by cautery and ultraviolet and infrared rays. The burns on the nose had become confluent, and an ulcer had been present which would not heal.

There was a crusted lesion over the tip and lower part of the nose, about 2 cm. in diameter, with some extension into the nasal cavity. The condition clinically was a low-grade squamous-cell epithelioma, which had developed in a roentgen-ray burn. The skin over the nose and forehead was very thin, almost like tissue paper, apparently the result of the roentgen-ray treatment.



Treatment of the epithelioma of the nose with surgical diathermy was recommended and this was done, February 16, under ether anesthesia. It was thought advisable to wait at least eight months before attempting reconstruction of the deformity that resulted.

The patient returned, October 23, 1928, for the reconstruction (Fig. 11, *a* and *b*). Although the skin over the forehead was very thin, it was thought that this was the most advantageous site for a flap. Skin from the arm was prohibited because of the profuse growth of hair. A flap was raised from the forehead October 24, and the middle portion of the flap was lined with a skin graft according to a method which I have described.[6]

a *b*

Fig. 11 (Case 6). Loss of the nose after removal of a squamous-cell epithelioma; *a*, anterior view; *b*, lateral view.

a *b*

Fig. 12 (Case 6). Postoperative appearance; (*a*), anterior view; *b*, lateral view; the reconstructed nose is shown; the nasal vestibules on either side allow free nasal breathing; there is lack of scarring of the forehead.

The last stage of the plastic work was completed, February 11, 1929. The length of time between the stages had to be increased, owing to the thinness of the skin and the fact that there was practically no subcutaneous tissue. Figure 12, *a* and *b*, shows the result. Cartilage was not utilized to raise the bridge of

the nose. This may be attempted if necessary at a later date.

Comment.—The difficulty of making a complete nose, as was done in this case, was a great problem until within the last few years, when the method of Nélaton, modified by Blair and reported by Ivy, made is possible to construct a fairly good looking nose in a comparatively short time. Although tissue from the arm or thorax may be used, the results are never quite as satisfactory as when a flap from the forehead is employed. It is best, in this type of case, to wait at least six months before attempting the completion of the plastic work, so that any shaping may be done, such as thinning out of the ala and columella and shaping up the nose laterally by removing subcutaneous tissue. In this case the skin was so thin that little was necessary, other than what was done at the time of the primary operation.

UDGA STOMACH TREATMENT

The formula of Udga is, apparently, secret—at least none of the advertising matter and follow-up letters give it. The Udga Medicine Co., which puts out this preparation, was formerly known as the Phungen Laboratories. The preparation is advertised as a mail-order treatment for stomach ulcer, gastritis and dyspepsia. From tests made in the A. M. A. Chemical Laboratory it appears that the preparation is similar in composition to the Pfunder Stomach Tablets which were found to contain bismuth subnitrate, magnesium oxide and sodium carbonate. (Jour. A. M. A., February 15, 1930, p. 504.)

THE COFFEY-HUMBER CANCER TREATMENT

The publicity, given through Hearst newspapers primarily, to the Coffey-Humber cancer treatment has brought about the very type of injury to scientific research that was predicted. Regardless of the fact that Drs. Coffey and Humber have made it clear that their work is purely experimental and that they do not claim to have developed a cancer cure, the great trek of cancer sufferers across the continent has begun and physicians everywhere are besought by their patients to procure this remedy. (Jour. A. M. A., February 22, 1930, p. 562.)

INTRAMUSCULAR IRON ARSENIC COMP. (NO. 201) AND (INTRAVENOUS) IRON, CACOD. AND GLYCEROPHOSPHATE (NO. 202) NOT ACCEPTABLE FOR N. N. R.

The Council on Pharmacy and Chemistry reports that a circular with the caption, "Formulas of definite therapeutic value," issued by Sci-Medico, Inc., New York, lists an extensive line of preparations marketed in the form of ampules and intended for intramuscular and intravenous administration and includes the following as having "proved useful in the treatment of anemia, nervous debility, neurasthenia, chlorosis and wherever a general tonic is indicated": (Intramuscular) Iron, Arsenic Comp. (No. 201), each 5 c.c. ampule being stated to contain Iron Cacodylate ¼ grain, Sodium Cacodylate ⅜ grain, Sodium Hypophosphite 3/16 grain, Manganese Hypophosphite 1/24 grain, Sodium Citrate ⅝ grain, and (Intravenous) Iron, Cacod. and Glycerophosphate (No. 202), each 5 c.c. ampule being stated to contain "Iron Cacod. (Colloidal)" 1 grain, Sod. Cacodylate 4 grains, Sod. Glycerophosphate 1½ grains. The Council declared these preparations unacceptable for New and Non-official Remedies because they are irrational mixtures marketed with unwarranted therapeutic claims. (Jour. A. M. A., December 7, 192, p. 1809.)

AFFECTIONS OF THE ROUND LIGAMENT WITH REPORT OF A CASE OF DOUBLE TUBERCULOUS HYDROCELE

E. Mendelssohn Jones, M.D., F.A.C.S.
Saint Paul

AFFECTIONS of the round ligament are comparatively rare and when present arouse a keen clinical and surgical interest. The round ligaments of the uterus are so frequently dealt with in routine surgical practice that one is apt to consider them merely as structures to be used in adjusting uterine displacements and overlook the fact that various types of pathological processes may develop in them.

Upon reviewing the literature one finds that affections of the round ligament fall into two general groups. In the first group are the tumors which develop in the tissues of the ligament; and in the other group are affections originating in the tissues closely associated with the ligament and drawn into the inguinal canal by it. This latter group includes the cysts and hydroceles of the round ligament.

Tumors are the most frequent affection of the round ligament and they may be either benign or malignant. These tumors are classified as intra-abdominal and extra-abdominal. The extra-abdominal tumors are further divided into: (1) intravaginal growths that push the posterior wall of the canal of Nuck forward and are therefore retroperitoneal; (2) intracanulicular growths situated between layers of the muscles without any connection with the vaginal process of the peritoneum, and (3) preinguinolabial growths situated in front of the external inguinal ring or even in the labia majora. These tumors usually develop in the extra-peritoneal portion of the ligament. The majority of these tumors resemble fibroids of the uterus in point of origin. Malignant tumors practically all consist of malignant degeneration of a fibromyoma and the small round cell sarcoma is the type most frequently found.

In 1914 Taussig[1] reported a case of spindle cell sarcoma of the round ligament and in addition collected five cases from the literature. He states that the round ligament sarcomata are slow growing and are only slightly malignant. He found no cases in which metastasis was described and was unable to find any record of recurrences after operation. In this group of six cases there was only one post-operative death, and that was in the first case recorded. Considering these findings one naturally would be rather encouraged regarding the prognosis in sarcoma of the round ligament, but in 1918 Mönch[2] reported a sarcoma of the round ligament which, within a few months, developed to the size of a child's head. The tumor was removed but the patient died eight weeks later from metastases to the abdomen and the brain. The very rapid course of development of this tumor and death following eight weeks later shows very conclusively the extreme malignancy of the growth. The glands removed at operation were small and showed inflammatory changes. Mönch[3] removed a tumor of the round ligament which proved to be a myofibroma undergoing sarcomatous degeneration. At the time of operation there was no evidence of sarcoma in either the ligament or the inguinal glands but the degree of malignancy of this growth was made evident by the patient's death eight weeks after the operation. It is fortunate that these cases of extreme malignancy have been brought to our attention for if we were to be guided by the results of the cases collected by Taussig our views as to the prognosis of sarcoma of the round ligament would be very optimistic until our ideas were changed by personal experience with this very malignant type of tumor.

In 1903 Emanuel[4] collected eighty cases of round ligament tumors and found that twenty developed intra-abdominally and the remainder were located either in the inguinal canal or the labial fold. Taussig[1] later added sixty-one cases, and of this number eighteen were intra-abdominal and thirty extra-abdominal. These tumors may be multiple and they occur three or four times more often on the right side than on the left. The intra-abdominal tumors usually spring from that part of the round ligament that is nearest the uterus and are very often pedunculated and give symptoms such as are caused by a subserous fibroid or a solid ovarian tumor. The size of these tumors varies considerably and they may be very large before any symptoms are

experienced. They usually assume a round or oval shape and are of a firm consistency.

Ward[5] reported a case of fibroid of the round ligament which weighed three pounds and eight ounces. This tumor arose 3 cm. from the horn of the uterus and the patient had been conscious of a growing mass in the abdomen for six months. The fact that these tumors may develop to considerable size in a comparatively short time is further shown by a most interesting case described by Taddei.[6] This patient had noticed a small hard mass in the right inguinal region for eighteen months and during the five months previous to her examination the tumor grew to the size of an egg-plant. He describes the tumor after extirpation as a fibromyoma. The rapid growth was verified by the microscopic examination as showing the connective tissue to be edematous and growing in between the smooth muscle fibers until the process reached a stage of a most accentuated lymphatic edema with the result that the muscle bundles of the tumor were disassociated.

Tumors in this locality have many of the same peculiarities as tumors developing in other parts of the body. This is shown by the foregoing cases in which a large tumor developed in a few months from a small quiescent nodule. It has been demonstrated further that the growth of these tumors may be stimulated at times by variout local influences. Soli[7] describes a case in which a small tumor had been noticed in the right inguinal region for eight years and this tumor did not change in size until the sixth year, at which time the patient became pregnant and after the fourth month the tumor began growing. It extended to the labia majora and became very painful. It has further been pointed out by Von Zur-Muehlen[8] that direct trauma may play an important role in causing these tumors to grow. Kolb[9] has described a case of fibromyoma of the round ligament that was found when the patient was operated upon for a fibromyoma of the uterus. Thirteen years previously a suspension operation was done for retro-displacement of the uterus. In attempting to explain the occurrence of this round ligament tumor Kolb states that the development of the uterine tumor caused tension on the round ligaments and at the point of attachment to the uterus some of the muscle cells were drawn away with the ligament and the development of the cells resulted in the fibromyoma of the round ligament.

Another type of tumor found in the round ligament is the adenomyoma, which is comparatively rare. This condition was first described by Cullen[10] in 1896. These tumors occur about four times more frequently in the round ligament than in the uterus. They usually are located in the region of the external ring and consist of a firm nodule intimately blended with surrounding adipose tissue. It is most commonly found during the child-bearing period, is slow growing and usually causes little annoyance until it becomes large enough to cause pain on walking or during menstruation. The discomfort evidenced on walking is explained by the intimate association of the tumor with the surrounding tissues. During menstruation these frequently increase in size and become painful, diminishing in size when menstruation ceases. The increase in size of these tumors during the menstrual period is supposed to be due to functioning of the glands as the contents of the glands removed at operation is frequently hemorrhagic. In a series of 141 tumors of the round ligament collected by Taussig there were nineteen cystic tumors found in which the cyst was surrounded by a fibromuscular tissue and three of these cysts contained blood and were classified as hematoma.

Cullen[11] states that there is a difference of opinion as to whether these tumors are derivatives of the Wolffian or the Müllerian duct. Some authors claim that portions of the Wolffian duct have been constricted off during the development of the embryo and have been carried down the round ligament and then developed in later life. They base their opinion on the fact that the Wolffian duct comes in close contact with the round ligament prior to its descent into the inguinal region. They further believe that the gland elements of the adenoma bear some resemblance to portions of the Wolffian duct. Those holding the other view feel that there is strong evidence that misplaced portions of Müller's duct are responsible for the growth of these tumors. It has been known that the glands in these adenomyomata often times cannot be distinguished from normal uterine glands. They are small, round, and lined with cylindrical ciliated epithelium and are surrounded by the characteristic stroma of the normal uterine mucosa. Another point in favor of the Müller's duct origin is that these adenomyomata resemble in every particular the diffuse adenomyomata of the uterus in which the glands are seen to be a direct

derivation of the uterine mucosa. There is no other place in the body in which mucosa similar to normal uterine mucosa is found and furthermore no other mucous membrane that periodically discharges blood. Cullen does not believe that it can be definitely stated that these growths are not derived from remains of the Wolffian duct but he believes the evidence is much in favor of the Müller duct origin. He cites a case in which menstruation commenced on May 18 and ceased May 23 or just three days before operation. On examination of the extirpated tumor the glands were found filled with fresh blood.

Dermoid tumors are found in many different localities but very rarely are they found involving the round ligament. Maccabruni[12] describes a case of a dermoid cyst connected with the round ligament. The condition was diagnosed as a probable right inguinal hernia of the ovary but this was changed to cystic tumor of the round ligament. The mass was the size of a pigeon egg, and gave no symptoms except pain during menstruation. The tumor was found to be so intimately connected with the right round ligament that the anterior portion of the ligament formed the posterior wall of the cyst. Maccabruni[12] brings out the fact that the tumor was formed of only one layer while the ovarian dermoids are formed of either two or three layers. As all extra-peritoneal dermoids spring from one layer he points out that it is probable this tumor arose from the ectodermic layer and progressed inwards invloving the round ligament secondarily.

The cysts and hydroceles of the round ligament may well be considered together as they both comprise a collection of fluid in the canal of Nuck. The hydrocele of the round ligament is not classified by Emanuel[4] as a distinct tumor development because it develops in the canal of Nuck and not from the tissues of the round ligament itself. The explanation of this process is clarified by a review of the anatomy[13] of the round ligament. The two round ligaments are rounded cords between four or five inches in length, situated between the layers of the broad ligaments in front of the Fallopian tubes. This ligament passes forward, upward and outward through the internal abdominal ring along the inguinal canal to the labia majora, in which it becomes lost. It consists principally of muscle tissue extending from the uterus, also of some fibrous and areolar tissue besides blood vessels and nerves enclosed in a duplicature of peritoneum in the form of a tubular process, for a short distance into the inguinal canal. This process is called the canal of Nuck. It is generally obliterated in the adult but sometimes remains patent even in advanced life.

The cystic affections of the round ligament are very apt to present more diagnostic difficulties than the tumors that have previously been considered. Tumors arising from the intraperitoneal portion of the round ligament may attain considerable size before giving rise to any symptoms and even then it would be very difficult to differentiate absolutely this condition from many types of pelvic tumors as the clinical picture is usually the same. In the early stage any affection of the extraperitoneal portion of the ligament is frequently mistaken for a hernia and very often these cases are fitted with a truss. Some authors feel that the wearing of a truss stimulates the growth of these tumors. The cysts and hydroceles of the round ligament are more difficult to differentiate from a hernia than are the hard, firm tumors.

In 1916 Hines[14] reported a cyst of the right round ligament. The patient noticed a swelling in the right groin and she complained of increasing tenderness in the mass. Examination showed a slightly fluctuating swelling, protruding from the external ring, which gave some tenderness on pressure. There was no cough impulse nor was there any signs of inflammation such as might be expected in acute adenitis or abscess. There was no intestinal symptoms suggestive of interference with the fecal current and no history of trauma. A tentative diagnosis was made of an encysted omentocele. At operation the tumor was found to fill the lower part of the inguinal canal and projected for some distance beyond the external ring. Hines believes that the cyst was due to an accumulation of fluid in the lower end of the canal of Nuck which may have been persistent through its entirety at one time and subsequently closed at some point in the inguinal canal. A very similar case is reported by Johnson[15] and at operation a hydrocele of the round ligament was found.

When the tumors or growths become larger and give rise to pressure symptoms with a dragging sensation and radiating pains down the legs

the difficulties of diagnosis are very much eleviated.

A diagnosis of any round ligament affection should be sufficient for us to advise operative measures. In the first place these small, apparently innocent nodules may in a short time develop to considerable size and in addition to causing the patient many troublesome symptoms the surgical removal becomes difficult. In the second place we know that the most common tumor of the round ligament is the fibromyoma and these tumors may at any time undergo a malignant change.

My interest in the affections of the round ligament was stimulated by the following case:

Miss L. P. came under my observation June 5, 1922. She is single, eighteen years of age, a student, and lives at home under very good conditions. Mother and father are living and well; two brothers also living and well. One sister died at the age of twenty from sarcoma of the uterus. Aside from minor ailments as a child the patient states that she was well until the Spring of 1921. At that time she suffered an attack of pain in the upper left chest anteriorly. This was accompanied by dyspnea. This lasted off and on until June of the same year, though it was never severe enough to keep her home from school. Her family physician made a diagnosis of dry pleurisy. In the Spring of 1922 this condition returned and affected the lower left chest anteriorly and laterally. She states that she still notices some slight discomfort in this region, especially on coughing. At the present time the patient complains of a swelling in both inguinal regions. On coughing there is pain across the lower part of the abdomen and in both inguinal regions. There is also dysuria and malaise. Menstruation is regular; duration five days; moderate flow; no pain. Last menstruation was May 10, 1922.

In March, 1921, she noticed a swelling in the left inguinal region. This was about one and one-half inches in diameter, soft, not tender and disappeared on pressure. There was no discoloration. This mass gradually increased in size. In March, 1922, she noticed a swelling in the right inguinal region. This likewise was about one and one-half inches in diameter and similar in all respects to the mass on the left side. It seemed to be increasing in size at about the same rate as the left side. About a year after the appearance of the mass on the left side she noticed pain in the inguinal regions and across the lower part of the abdomen when she coughed. This was the first discomfort she had experienced. In March, 1922, at the time the mass on the right side became evident, she was fitted with a truss with a pad on each side. About this time a marked dysuria developed. This consisted of a dull aching pain which occurred just at the completion of the act of voiding and lasted for two or three minutes. This pain was located in the lower abdomen and was more especially felt in the swellings in the inguinal regions. This pain was so severe that she had to assume a bent position for relief. This pain has persisted to the present time and has neither increased nor decreased in severity. Patient states that for the past few months she has tired more easily and she feels under par.

Physical examination.—The patient is a well developed and well nourished female but appears somewhat anemic. Weight 140 pounds. Temperature normal. Pulse 86. Systolic blood pressure 108; diastolic 72. Head and neck normal. Lungs show no areas of dulliness and there is a normal respiratory murmur throughout. Heart not enlarged. No murmurs. Abdomen is flat. No scars. No areas of tenderness. No masses palpated. Rectal examination revealed the uterus in anterior position, movable, not enlarged. No masses or tenderness found in the adnexal regions. Examination of the inguinal regions showed the external rings to be relaxed and large. On inserting the finger into the canal a fullness was found that could not be completely reduced. When patient coughed a slight impulse was felt. When patient stood up a mass presented at both external rings. These masses were soft, not tender, and could be reduced into the canal. The mass on the left side was about a third larger than the one on the right side. Urine examination negative. Blood normal. A diagnosis was made of bilateral inguinal hernia with probable involvement of the bladder. Operation was advised.

Operation June 6, 1922, at the Ancker Hospital under local anesthesia. The right side was operated upon first. The usual incision for repair of an inguinal hernia was made. When the inguinal canal was opened a soft, apparently cystic mass was encountered. It extended to the external ring and was not reducible. The distal portion of the mass was first freed and the dissection carried upward. There were places where the wall was very thin and the cavity of the mass was opened at one point where it was densely adherent to the floor of the canal. The opening was immediately closed but a small amount of straw colored fluid escaped. When the mass was entirely freed it was found to lead to the internal ring. The peritoneum was located and was apparently normal and not involved in the pathologic process. The mass was then clamped at its lower limit and removed. The wound was closed in layers with cat gut sutures. There was some doubt in our minds as to the exact condition with which we were dealing and considering the possibility of a vesicle diverticulum a small soft rubber drain was introduced extending below the fascia. The left side was then operated upon and the same condition was found and was treated in the same way. An indwelling catheter was placed in the bladder. As soon as the examination of the removed specimens revealed the fact that no bladder tissue was present the indwelling catheter and drains were removed. Convalescence was uneventful and patient was discharged from the hospital June 19, 1922.

Pathological Report.—The specimens of tissue removed from the right and left inguinal canals consist of two cyst-like sacs with an outer rough layer and an inner smooth shining serous layer. These were

opened at one end and measured 7 × 3 and 9 × 4 cm., respectively. The walls are of variable thickness, ranging from 1 mm. to 3 mm. and appear transparent in the thinnest portions. Cross section shows the left to be multilocular and the right to be unilocular. The lumen is filled with a yellow, gelatinous material. The inner lining is smooth and shining but is thrown into irregular folds, is dark red in color and studded by minute yellowish nodules varying from 1 mm. to 2 mm. in diameter. These are firm in consistency and quite typical of miliary tubercles. Microscopic section shows the walls to consist of connective tissue carrying many blood vessels which are dilated and filled with blood. There are also a number of small hemorrhages into this tissue, and the occasional appearance of a few smooth muscle fibers. Scattered throughout are numerous tubercles characterized by endothelioid cells, giant cells and a rich infiltration with lymphocytes.

Diagnosis.—Tuberculous serous cysts.

After considering all the findings in the case a post-operative diagnosis was made of tuberculous hydrocele of both round ligaments. The two most important conditions forming a cystic tumor in this locality to be considered were adenomyoma and hydrocele of the round ligament. The pathological examination furnishes no evidence of an adenomyoma but it does show a cystile mass whose wall is formed by serous membrane. Such a finding in this region points at once to an accumulation of fluid in the canal of Nuck. The writer believes that in this case the canal of Nuck has remained patent and later became closed at some point in the inguinal canal and the incidence of the tuberculous infection at this point resulted in the development of the tuberculous hydroceles. It is impossible to determine the origin of this infection but the most reasonable presumption is that the attacks of pleurisy from which the patient suffered were due to a previous tuberculous infection which has since healed and become inactive. A most thorough search, both by physical examination and roentgen plates, failed to reveal any focus in the lungs. It is very probable that the primary focus was in the hilus and therefore difficult to demonstrate.

A very logical question arises as to the presence of any intra-abdominal tuberculosis which could have extended along this persistent peritoneal process. The patient has never had any disturbance or symptoms which a tuberculous infection of the pelvic organs, sufficient to give rise to such an advanced involvement as we have in this case, would produce. The patient undoubtedly would have had some symptoms directing our attention to this region and positive evidence would have been found on pelvic examination. The same facts apply to the question of a general abdominal tuberculosis. The peritoneum that was inspected at the internal ring, on both sides, at the time of operation was apparently perfectly normal. In an extensive search of the available literature I was unable to find any reference to the incidence of tuberculosis in connection with hydrocele of the round ligament. This is, then, as far as I am able to ascertain, the only case of tuberculous hydrocele of the round ligament to be reported.

CASE REPORT

THE DIFFERENTIATION BETWEEN ACUTE APPENDICITIS AND ACUTE PROSTATITIS AND SEMINAL VESICULITIS*

REPORT OF TWO CASES

WILLIAM P. HERBST, M.D.
Minneapolis

I would not venture to estimate the number of male patients who have undergone appendectomy for acute prostatitis and seminal vesiculitis, but they make up a much larger group than most of us would care to admit. Inasmuch as I have seen two cases recently in which the appendix was suspected, I am bringing this subject before the Society.

Chronic prostatitis and seminal vesiculitis occur in some degree in about 30 per cent of all adult males, and in only about 60 per cent of these is there an antecedent history of gonorrhea. When one takes into consideration the number of cases in which gonorrhea is superimposed upon a previously existing prostatitis and seminal vesiculitis, a reasonable estimate of prostates and vesicles infected primarily by the hematogenous route would be about 70 per cent.

The more common causes of non-venereal prostatitis are infected teeth, infected tonsils, and infected nasal sinuses. Less frequently, but nevertheless a factor in some cases, is intercourse with individuals harboring pathogenic organisms in their cervical secretions.

The results of cultural studies made by von Lackum in 405 cases in which prostatic secretions were examined were as follows:

Sterile	35.25 per cent
Streptococci	35.25 per cent
Staphylococci	22.25 per cent
Other organisms	7.25 per cent

Of infected cases, streptococci constituted 55 per cent, staphylococci 33 per cent, and other organisms 12 per cent.

In determining the presence or absence of prostatitis, a most satisfactory procedure is to examine microscopically some of the prostatic secretion obtained after prostatic massage with the bladder empty. The failure to obtain secretion is indicative of pathology and not of the absence of pathology, as is so commonly thought.

The lighting up of these chronic prostatic and seminal vesicular infections into acute conditions occurs in a certain number of cases and often suggests acute appendicitis, as is shown in the two following case histories.

Case 1.—Mr. E. M., thirty-seven years of age, married thirteen years, had gonorrhea ten years ago. He had had frequent sore throat. Two months before I was called to cystoscope him for pyuria with fever and lower left abdominal pain, he had an acute throat infection which was followed by abdominal pain which varied in location and for which one doctor had recently (within the previous week) advised appendectomy. When I saw him his complaint was lower left abdominal pain with slight nausea. His temperature was 99.4 degrees; pus (grade 1) was present in the urine and some tenderness (for the past few hours) in the left epididymis. W.B.C., 35,000. There were no urinary symptoms. The tonsils were red and cryptic. There was moderate tenderness throughout the abdomen, but this was more marked in the left lower quadrant. The left epididymis was quite tender. The prostate was normal in size with multiple indurated areas, and was exquisitely tender. The left vesicle was more tender than the right, but both were normal in size and consistency. The prostatic secretion was practically pure pus. I did not cystoscope him on account of the acute epididymis and the comparatively small amount of pus in the urine.

Following a somewhat stormy course, which was ushered in by the interne giving 5 c.c. of a stock vaccine instead of 3 minims, the acute condition gradually subsided so that the patient left the hospital in eight days. His tonsils were removed about three weeks later and although he has not followed advice as to adequate treatment for his prostatitis, it was reduced to a Grade 1 infection with pusless urine without further local treatment. His treatment could not be handled satisfactorily owing to the fact that he is a traveling salesman.

Case 2.—Mr. L. C., twenty-five years of age, medical student, had had scarlet fever and diphtheria in childhood, and occasional attacks of tonsillitis each year. No history of gonorrheal infection.

The onset of the attack was sudden, with headache, malaise, fever and chill, temperature of 103.8 degrees, pulse 120, and slight abdominal discomfort. The W.B.C. count was 14,000. The urine was negative. The tonsils were moderate in size and injected.

The next day when I saw him he felt about the same, but the temperature had fallen to 99.4, and the leucocyte count was 25,000. The abdomen was negative except for a generalized sensation of discomfort. The prostate per rectum was normal in size and consistency. The vesicles were normal in size and consistency but were extremely tender, especially the right, and pressure here produced a very severe pain in the right lower quadrant. Secretion obtained contained pus (grade 3), and the urine contained pus (grade 1).

The condition continued as a mild general abdominal discomfort, with occasionally transient frequency, pyuria from grade 1 to 3, and with a gradually receding leucocyte count under urinary antiseptics and semi-ambulant regime. A cystoscopy was done to rule out

*Read before the Minneapolis Surgical Society, at its meeting of November 7, 1929.

a small *x*-ray shadow in the right lower pelvis as a possible stone, and to obtain definite information as to the source of the pus. The urine from both kidneys was negative, and that from the bladder contained pus (grade 1). The shadow in the *x*-rav was demonstrated to be extra-urinary by the right pyeloureterogram.

This condition continued about the same for the next three weeks. On one examination I found what I thought to be definite tenderness over the appendix, and felt that he might have an infected appendix in conjunction with his prostatitis and vesiculitis. He had his appendix out as an interval appendectomy, and it was described as a retrocecal congested appendix, but it gave no evidence of inflammation upon very careful microscopic examination of sections.

About three weeks later he had his tonsils removed as an aid in doing away with a probable etiological factor in his prostatitis and vesiculitis.

In conclusion I wish to call attention to the occurrence of a leucocytosis in these cases and to mention the part the tonsillar infection may have played. I wish also to urge rectal palpation and microscopic examination of the prostatic secretion in all patients whose clinical picture does not conform to the typical acute appendicitis sydrome, before appendectomy is performed.

SOME ENERGEN FOODS NOT ACCEPTABLE FOR N. N. R.

The Council on Pharmacy and Chemistry reports that a line of "Energen" products, marketed by the Energen Foods Co., Ltd., England (Energen Foods Co., Inc., New York), distributor), was presented for consideration as "starch reduced" foods containing "an increased amount of protein in the form of gluten" and recommended for use in the dietetic treatment of "Diabetes, Obesity, Gastric and Intestinal troubles, in which it is essential to decrease the amount of starchy food, and in all conditions of debility or malnutrition where an increase of proteins is necessary." The Council found many unwarranted claims and other objectionable statements in the submitted advertising material. When these were reported to the firm, it stated that some of this advertising is no longer in use even in England and most of it has not been circulated in the United States. Assurance, however, was given that the advertising matter to which objection had been made has been discontinued or that it will be. The firm requested reconsideration, particularly of Energen Bread, submitting further advertising. After considering the further evidence, the Council declared Energen Bread, together with Energen Bismeal, Energen Cocoa, Energen Digestive Biscuits, Energen Endobran Biscuits, Energen Gluten Semolina, Energen Gluten Tapioca, Energen Macaroni, Energen Pastry Flour, Energen Starch-Reduced Bread (Batons), Energen Starch-Reduced Bread with Casein (Batons), Energen Starch-Reduced Rolls, Energen Starch-Reduced Rusks, Energen Starch-Reduced Wheatmeal Bread (Batons), unacceptable for New and Non-official Remedies because they are unscientific mixtures marketed with unwarranted therapeutic claims under names not correctly descriptive of their composition and in a way to invite their ill advised use by the public. (Jour. A. M. A., August 3, 1929, p. 381.)

THE TWENTY-FIFTH ANNIVERSARY OF THE COUNCIL ON PHARMACY AND CHEMISTRY

At a meeting held February 3, 1905, the Board of Trustees of the American Medical Association created an advisory board to be known as the Council on Pharmacy and Chemistry. The organization of this Council was perfected on February 11, 1905. Thus the Council on Pharmacy and Chemistry passes the twenty-fifth year of its organization and continues, in a second quarter century, one of the most notable works for scientific medicine ever accomplished by any organized group. It is significant that several of the original members of the body have maintained their connection since its inception and that the secretary, W. A. Puckner, has rendered continuous service as a full-time officer for the body from the first. The Council could not have achieved what it has, without the support of the medical profession of our country. Thus, with the establishment of the Council, the advertising of medicinal preparations in the Journal of the American Medical Association was limited to those products that had been passed by the Council. The same rule has applied to the other publications of the Association, and finally every state medical journal, except those of Illinois and New York, followed this lead. A considerable number of journals not controlled by medical societies also give their support to the Council's work. The medical profession must support the Council or its work will be futile. The members of the Council serve without remuneration and The Journal of the American Medical Association tenders to them the thanks and appreciation of the profession that they have so well served. (Jour. A. M. A., February 8, 1930, p. 413.)

President's Letter

PROBABLY the greatest need today of the rank and file of the medical profession is contact with each other, because contact brings an exchange of experiences and ideas. This stirs latent memories, inspires new interest in one's work, fosters good fellowship, promotes tolerance and respect for each other, teaches us to know our own shortcomings and to recognize the sterling worth of our professional neighbors.

Wherever men with common interests and purposes gather together to learn from each other, they soon discover that petty differences which had once kept them apart lose their magnitude in a new perspective or completely vanish amid the bigger and better things born of the collective search for knowledge. Surely it is permissible in this connection to quote from the Presidential Address by William Osler before the Medical and Chirurgical Faculty of Maryland: "No class of men needs friction so much as physicians; no class gets less. The daily round of the busy practitioner tends to develop an egotism of a most intense kind, to which there is no antidote. The few setbacks are forgotten, the mistakes are often buried, and ten years of successful work tend to make a man touchy, dogmatic, intolerant of correction, and abominably self centered. To this mental attitude the medical society is the best corrective, and a man misses a good part of his education who does not get knocked about a bit by his colleagues in discussions and criticisms."

A masterly expression is it not? But it applies to a considerable number of us, in the cities as well as in the country. Where it applies in the cities it is a greater reproach, for there contact is easily had with one's fellows. Whereas in the rural districts the doctors serving an extensive territory may be so widely scattered that, despite good roads and autos, a real sacrifice may be suffered in getting together. Yet the sacrifice is more than compensated by the resulting mutual understanding of each others problems, both social and scientific. It has been said that every doctor is known to be a thoroughly good fellow by everybody else except another doctor. If that be so then we doctors are allowing some very small personal envies and jealousies to cheat us out of the greatest of kindly sympathies, companionships and friendships that our poor human society has to offer.

The next meeting of the state society will be held July 14, 15 and 16 in Duluth.* The secretaries and presidents of the component societies can render their members a valuable service by persuading them to attend this meeting. Moreover the councillors, committee chairmen and officers of the state body wish to meet as many of the members as possible. They wish to talk over our common problems. They wish to learn at first hand what the men are thinking, what they want, how they think we can render our organization more serviceable both scientifically and socially.

S. H. Boyer

President,
Minnesota State Medical Association.

ARE THE STATE DUES EXCESSIVE?

We are all concerned about the high cost of living. The question, however, of keeping expenditures within the limits of income resolves itself in most instances into the use of judgment in the matter of expenditures. The sum total of money foolishly spent by people in general is appalling. We physicians both individually and sometimes collectively are not exceptions in this respect.

The question has been raised in various quarters whether the money being spent by our State Association (and the yearly total has shown a marked upward trend in recent years) is being wisely expended. The Council of the State Association is the financial body of our organization and authorizes the expenditure of the income of the Association which for the most part consists of the dues voted by the House of Delegates. We members therefore, through our self-assessment have made possible the rather considerable sum available the past three years. The House of Delegates, realizing the need for more funds if the proposed program of expansion was to be carried out, voted the increase of state dues to $15.00 effective in 1927. Some members have begrudgingly paid the dues, but apparently few if any have given up their membership on account of the dues, judging from the membership roll, for in 1929 our membership was the largest in history.

Now just what has been accomplished with the $15.00 membership?

In the first place we have a real organization and a secretary in Dr. E. A. Meyerding who has not only the ability but the time to devote to Association affairs. We have a long list of committees that have been conscientious in tending to their duties and have undoubtedly been more efficient because of the aid given them by the organization in general and the secretary in particular.

The committee which has accomplished the most and naturally has spent the most, has been the Legislative Committee. Not one man in a thousand could or would have done the work that Dr. Herman Johnson has done with the legislature the past few years. And what has this committee accomplished? The prevention of undesirable legislation is usually the major part of legislative accomplishment and when it comes to legislation affecting medical affairs there has been no exception. Almost yearly the wild reformers calling themselves anti-vaccinationists and anti-vivisectionists have to be combatted; the establishment of new cults prevented; and the extension of the rights of medical cults already licensed has to be curtailed.

In 1925 this committee obtained a reduction in the statute of limitations from six to two

years to conform to the statutes in force in most of the other states of the union. The long period of six years has been responsible for the high incidence of malpractice suits in Minnesota which had reached such a point that one insurance company operating in the state was about to materially increase its rates. The yearly saving to physicians in this state has undoubtedly amounted to more than the full amount of our present state dues.

The Basic Science Law went into effect May 1, 1927. Since that time but two chiropractors and only twenty-one osteopaths have passed the Basic Science examinations, while during the five preceding years an average of forty-three chiropractors were yearly licensed in Minnesota. Fifty-one osteopaths were licensed during the six year period prior to this act. The law has apparently had the desired effect of barring the unqualified from becoming licensed in this state in the future.

The revision of the Medical Practice Act in 1927 effected certain needed changes in the old law. The yearly fee for registration of physicians has furnished the means of enforcement and that this means has been utilized is shown by the report of the investigating attorney that in less than two years ninety-eight cases have been investigated and twenty-seven cases brought into court with twenty-three convictions.

If it had not been for the legislative committee tax supported hospitals would have been opened to the medical cults; the laboratory of the Venereal Division of the State Board of Health would probably have been discontinued and a limit would have been placed by law on medical fees coming under the Industrial Commission.

The next most expensive committee of the Association has been the one on Public Health Education. The activities of this committee have been so diversified and its influence has been exerted in so many directions that the results are less tangible. They undoubtedly are nevertheless far reaching. The efforts of this committee have been to foster medical influence in the direction of the various health organizations in the state. This has been accomplished in part through county society committees on Public Health, by assisting health organizations in putting on approved programs and by assisting the Minnesota Public Health Association in the preparation of its publications and otherwise. Weekly newspaper service has been conducted throughout the state and radio talks have been furnished.

One of the worthwhile undertakings of the Association which should be mentioned is the Consultation Bureau conducted by Dr. W. A. O'Brien in Minnesota Medicine. The county secretaries' conference has been made possible by the increase in dues and the annual meeting is no small item of expense.

While we do not approve of extravagant expenditures by the State Association the above recital seems to substantiate the view that there has been value received. The whole question is whether we are to continue to be an organization which through its various agencies is going to make its influence felt, or whether the State Association is to revert back to its former condition of innocuous desuetude.

SCHOOLS FOR TECHNICIANS

The demand for X-ray and laboratory technicians has opened a new and attractive field, especially to young women with high school education and even in some instances to those with college degrees. The training of these technicians has presented certain problems which so far have not been solved.

The Council of Medical Education and Hospitals of the A. M. A. has investigated laboratories all over the country and has published a list of the laboratories they have approved as satisfying certain minimum requirements. Our University has in operation a four year course for the training of technicians. The real problem lies in the existence of laboratories which furnish poor training for technicians. Some of these institutions have been established by lay individuals, have no hospital connection and have therefore no methods of obtaining laboratory material for instruction, have a faculty composed of technicians or poorly qualified physicians, and are purely commercial enterprises. High pressure advertising methods are used and extravagant or dishonest claims made as to the kind of instruction furnished and the high salaried jobs awaiting graduates. Glowing accounts are given by field agents to groups of high school students in an effort to swell the enrollment of the school.

The present unsatisfactory situation was brought up in the House of Delegates at the last

State Medical meeting. The opinion was expressed that the State Association should take some steps to prevent the continuation of these humbug institutions in our state. The proposal that a committee of the State Association should issue certificates to technicians who had received proper training was wisely rejected when it was brought out that the State Association after issuance of such a certificate would not be in a position to use disciplinary measures if necessary. A State Committee on Schools for Laboratory Technicians was however appointed to investigate the situation and report at the next meeting.

This is a matter with which our Legislative Committee will doubtless be concerned as a bill was introduced in the last legislature proposing to regulate these technical schools. It failed to pass on account of certain technicalities, but is likely to be resubmitted at the next legislature. As Dr. Morris Fishbein stated at our last state meeting, there doubtless should be some legislative provision for the chartering of such schools. Just how this control should be exerted is a matter that deserves some consideration.

There is no question but that the director of an *x*-ray or medical laboratory which trains technicians should possess the background of a medical training. Isolated laboratory reports are dangerous. The supervision of laboratory training by an M. D. is also important in order to instill the proper viewpoint in the undergraduate mind. It goes without saying that the physician in charge should be in good standing in the medical profession.

PROTECTING CHILDREN FROM TUBERCULOSIS

The month of April has again been chosen by the National Tuberculosis Association for its annual prevention campaign. The above title is this year's slogan and a good one it is, for if the infants and children of today can be protected from the infection until adult age is reached a major problem in the anti-tuberculosis campaign will be solved.

Students of tuberculosis have changed somewhat their interpretation of the course of tuberculous infection. Many patients suffering from tuberculosis give a history of exposure to the infection in infancy and childhood with good health until early adult life is reached. On the other hand in many instances of adult tuberculosis the exposure is never traced. While most adult tuberculosis is the result of an infection early in life, an appreciable percentage of cases undoubtedly acquire the infection after the age of twenty.

From a practical standpoint the protection of infants and children from infection is a most important procedure in a prevention campaign. It is only through publicity measures that progress in this line can be made, and even though reiteration of the seriousness of the disease is likely to bring out neurotic tendencies in those so disposed, the campaign must be pushed.

The public is gradually being impressed with the potential seriousness of a chronic cough. Grandpa with his hacking cough is persuaded to be examined. The cigarette cough may not be as harmless as supposed. The affectionate friend who insists on kissing children and on the mouth too is most unpopular with the young mother of today—and rightly so.

A pamphlet entitled "Childhood Types of Tuberculosis" just made available by the National Tuberculosis Association and which can be obtained from the Minnesota Public Health Association is a gem. It contains a rather reliable answer to the prevalence of tuberculosis in this country. An analysis of 51,000 school children below high-school age in cities and towns in Massachusetts showed that 28 per cent reacted to the tuberculin test; 1.5 per cent had childhood types of tuberculosis, and 3.4 per cent were classed as suspicious. The blanket statement that we all become infected with tuberculosis at some time or another is obviously erroneous.

One word of warning should, however, be uttered. The pamphlet mentioned states that "calcified lesions in children, however, indicate tuberculous disease." This statement, we feel sure, is not in accordance with the opinion of all authorities on this subject. Certainly the physician who is unfamiliar with the appearance of the *x*-ray of a normal child's chest has no right to cause unnecessary anguish on the part of a mother by a too ready diagnosis of pulmonary tuberculosis from an *x*-ray plate of the chest alone. Calcified glands at the hilus in a chest *x*-ray of a child with a positive tuberculin test may be the result of a tuberculous infection, but

it should be kept in mind that the shadow of a bronchus at the hilus may simulate a calcified gland. *X*-ray diagnosis of active pulmonary tuberculosis (requiring treatment) is in general an unsafe procedure, and this statement applies to early infancy and childhood.

ASSOCIATE EDITOR

The Journal has been very fortunate in having had the services of Dr. Frederick W. Schlutz, Chief of the Pediatric Department of theMedical School, as associate editor for the past five years. He has had charge of the Progress Section of the journal, a department which should be of considerable interest to our readers, although conducted on a small scale as compared with the corresponding department in certain other journals. This department in Minnesota Medicine deserves more attention on the part of physicians throughout the state and it seems necessary from time to time to call attention to the fact that abstracts of current literature by members of the association are always welcome. Those interested are urged to get in touch with the nearest department head so as to avoid duplication.

With the departure this month of Dr. Schlutz to Chicago, his place will be taken by Dr. Lewis M. Daniel of Minneapolis. Dr. Daniel has been the editor of the new Hennepin County Bulletin and has kindly consented to assist with the editing of Minnesota Medicine. Heads of the various sections should submit abstracts directly to Dr. Daniel, 1853 Medical Arts Building, Minneapolis.

T-A YIELDS SUBSTANTIAL RETURNS IN YONKERS

From January 1, 1926, to January 1, 1930, 20,538 children in the city of Yonkers were immunized against diphtheria. This resulted in a large reduction both in incidence and mortality, the former decreasing from 431 in 1927 to 66 in 1929, and the latter from 23 to 5 during the same period. Because of this diphtheria prevention work there was a marked decrease in the number of diphtheria cases treated at the Communicable Disease Hospital during 1929, resulting in a reduction in the amount spent by the hospital during the year of approximately $7,500.

The anticipated saving during 1930 over the amount spent during 1929 has been estimated at $9,400.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

GRANITE FALLS WOMAN GIVEN JAIL SENTENCE FOR VIOLATING BASIC SCIENCE LAW

Marie Pederson, forty-two years of age, residing at Granite Falls, Minnesota, entered a plea of guilty to practicing healing without a basic science certificate.

Mrs. Pederson has been at Granite Falls intermittently for the past four years. She maintained an office in her living quarters on the East side of the river in Chippewa County. She was popularly referred to as the "Iodine Nurse." Several complaints were made to the State Board of Medical Examiners in reference to this defendant. After an investigation by Mr. Brist on behalf of the Board, she was arrested and entered a plea of guilty. The Court sentenced the defendant to a term of 90 days in the Chippewa County jail, and placed the defendant on probation upon the condition that the defendant absolutely refrain from practicing healing in this State. The defendant's home is at Brandt, South Dakota.

Before sentencing the defendant, Judge Baker exacted a promise from the defendant concerning her conduct in the future, and made it very plain that she would serve every day of her sentence if she attempted to practice in this State in the future.

MINNEAPOLIS WOMAN CONVICTED OF VIOLATING BASIC SCIENCE LAW

Mrs. Kathyrn Albers, 2527 Hennepin Avenue, Minneapolis, went on trial February 10, 1930, before a jury in the Court of the Honorable Gunnar Nordbye on a charge of practicing healing without a basic science certificate. The testimony disclosed that Mrs. Albers was using electrical appliances in giving treatments. Her defense was that she was exempted from the basic science law because she gave "mental and spiritual treatments."

The Court ruled, however, that the kind of treatments given by the defendant was a question of fact for the jury, and after deliberating only twenty minutes, the jury returned a verdict of guilty.

On February 13 Judge Nordbye sentenced the defendant to six months in the workhouse, and placed her on probation for one year. The defendant was given thirty days from that date in which to dispose of her equipment and get out of the business.

In event she does not comply with the order of the Court, the defendant will have to serve her workhouse sentence.

Judge Nordbye gave the jury a very splendid charge, and instructed them that the case was a very important one from the standpoint of the people in this State, and deserved the most serious consideration on the part of the jury.

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 10:15 o'clock every Wednesday morning over station WCCO, Minneapolis and St. Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of April will be as follows:

April 2—Cancer Cures
April 9—White *vs.* Brown Bread
April 16—Safeguarding Motherhood
April 23—Code of Medical Ethics
April 30—Inflammation of Mastoid Bone

MINNEAPOLIS SURGICAL SOCIETY

Dr. A. T. Mann was elected president of the Minneapolis Surgical Society at the annual meeting held in March. He succeeds Dr. S. R. Maxeiner. Dr. Theodore Sweetser was named vice-president to succeed Dr. M. J. Lynch. Dr. H. O. McPheeters was re-elected to the position of secretary and treasurer.

Dr. J. M. Hayes was named to serve on the advisory committee for five years, while Dr. Owen Wagensteen was elected for four years to fill the unexpired term of Dr. Sweetser. Other members of the council are: Drs. R. C. Webb, W. D. White, E. Robitshek and S. R. Maxeiner.

MINNESOTA STATE MEDICAL ASSOCIATION

DULUTH MEETING

"The best scientific program in the history of the organization is in preparation for the Sixty-second Annual Meeting of the Minnesota State Medical Association," President S. H. Boyer announced following the final meeting of the Committee on Scientific Assembly, March 22.

The meeting will be held in Duluth July 14, 15 and 16. A series of vitally important subjects will be discussed and a distinguished group of visiting celebrities will be present to make it a program no medical man can afford to miss.

It is expected that Dr. Volhartt of Germany and Dr. W. T. Longcope, professor of medicine, Johns Hopkins, will be present. They are scheduled to talk on diseases of the kidney.

The symposium on early carcinoma, one of the livest subjects before the medical profession today, will have W. J. Mayo, F. A. Figi and Waltman Walters of Rochester, and Leo Rigler and O. J. Campbell of Minneapolis to lead the discussion.

The symposia on Traumatic Surgery, Immunology, Rheumatic Fever and Anesthesia, scheduled also, will have equally distinguished attention.

The scientific aspect of the meeting will conclude with the symposium on Therapy led by such men as E. C. Davidson of Detroit on the "Treatment of Burns in Children," and R. S. Dixon, also of Detroit, on the "Treatment of Gonorrhea in the Female."

In response to a large number of requests the committee has arranged to present the Canti Cancer Film again as well as other new films of scientific interest.

Space does not permit full details of the important scientific program. But every member of the Association will look forward to the early publication of the complete printed program.

The first business session of the meeting is that of the Council scheduled for Sunday night, July 13, with the House of Delegates convening Monday. Medical fraternities and alumni associations of the University of Minnesota are planning meetings to coincide with this session.

Trends in modern medicine, where they are leading and what they hold in store for the regular practitioner will be discussed Monday night by Olin West, secretary of the American Medical Association; J. G. Crownhart, secretary of the Wisconsin State Medical Association; W. J. Burns, secretary of the Wayne County, Michigan, Medical Society; Paul Fesler, superintendent of the University Hospital; N. S. MacDonald, U. S. Veterans Bureau, and Mrs. F. L. Adair.

The banquet scheduled for Tuesday night will have W. A. O'Brien, University of Minnesota, for toastmaster. President Boyer announces that he hopes to have all living past presidents of the Association present at a special table for this occasion which is to be devoted to a good time for everybody with little, if any, speaking.

W. A. Coventry of Duluth, in charge of the local committees on arrangement, has appointed many subcommittees to look after the welfare of members and their wives. Arrangements for the Women's Auxiliary are in the hands of Mrs. F. W. Spicer and Mrs. B. F. Davis. Duluth members announce that they expect to make this the most delightful as well as the most interesting meeting in the history of the Association.

VITAMIN D IN TUBERCULOSIS

A recent investigation of the role of vitamin D in the management of tuberculosis indicated that the administration of viosterol did not produce any detectable acceleration of the healing process. These observations suggest that such value as cod liver oil possesses in tuberculosis does not depend on its relatively high concentration of vitamin D. These studies emphasize the fact that cod liver oil possesses more than one claim to nutritive value, for it is even richer in vitamin A than in the antirachitic factor. In spite of the enormous antirachitic potency of viosterol, this material is by no means to be regarded as therapeutically equivalent to cod liver oil. (Jour. A. M. A., February 8, 1930, p. 414.)

A PAGE FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

Medical Science in the Soviet

Available information on the state of socialized medicine in Russia shows a curious picture of a progressive idealism on the one hand and bitter class feeling on the other.

The apparent result is a large and ostensibly progressive organization for care of the sick resting upon an entirely inferior, unsuitably selected and badly educated medical profession.

Whether that is the inevitable result of socialized medicine or of the particular bitterness with which the professions are held in Soviet Russia, the reader is left to guess.

Dr. Ralph Reynolds, retired president of the American Medical Association in Vienna, visited a large number of clinics in Moscow and Leningrad recently.

He told the New York Herald-Tribune on his return that all Soviet workers are insured so as to provide medical care as well as full wages while they are sick.

Night sanatoriums for workers who are in poor physical condition in which the worker gets special diet and exercises and treatment if he needs them are flourishing. There are twenty-four of them in Moscow, ten for tuberculosis suspects. There are also 156 day nurseries, most of them located near the factories where the mothers are employed. Large numbers of physicians are on duty night and day at the public clinics. And there is ample provision and equipment for research.

On the other hand, all physicians are employed by the government and at a considerably lower wage than that paid the sovereign worker of the Soviet. This latter-day aristocrat will no longer hear of well paid professions which give the doctor or the lawyer a better home than he is able to earn.

Consequently even the best paid doctor seldom earns more than 100 dollars a month and is obliged to live accordingly, and a generally inferior class of students is entering the medical schools. In spite of the funds lavished by the government on equipment and instruments, scientific research inevitably leaves much to be desired, too.

The American doctor obviously looked with suspicion upon a system which manned even the most up-to-date and well equipped public health systems with inferior, badly educated and under-paid physicians.

An interview with the Grand Duke Alexander of Russia, published recently in the Illinois Medical Journal, affords another interesting, though possibly biased slant on the social state of things in Soviet Russia.

The grand duke's quarrel with the Soviet is not political, he insists. He is the present tenth in succession to the throne of the Romanoffs but declares that if by any strange hazard the ancient Romanoff power should be put in his hands, he would immediately deposit it in a Russian republic.

His quarrel is with the social teachings of that curious, half legendary revolutionary figure, Madame Kollontai.

"How many of you here in the United States know the truth or half the truth about the 'reforms of Russia'? Such reforms as teach little girls who should yet be learning their prayers that the sex act and its consequences need not worry them?

"What have we in Russia? Little girls, some of them as young as eight and ten years, openly having connections with men and knowing even at that age that the right of abortion is as free and easy as the right to drink water!"

This state of affairs he lays at the door of Kollontai and warns Americans of hidden germs of the same teachings in much of the proposed first aid to mothers and children legislation in the United States.

It is interesting to note that this exiled Russian of the ancient aristocracy has three sons employed in this country, one as a bond salesman in New York; another as a department store clerk in Chicago; a third engaged in aviation manufacture. The duke, himself, lectures occasionally, upon the romantic vicissitudes of his life.

OF GENERAL INTEREST

Dr. Arthur Strachauer, Minneapolis, has resigned as Director of the Cancer Institute at the University. He retains his title as Professor of Surgery in the Medical School.

Miss Marion Vannier has resigned as Director of the School of Nursing at the University Medical School, effective September 1, 1930. Her successor has not yet been appointed.

Dr. Royal C. Gray of the University of Minnesota, Department of Mental and Nervous Diseases, left the latter part of March for Boston, where he will do post graduate work in the Boston Psychopathic Hospital.

Dr. Arthur Garbrecht, formerly associated with the Earl Clinic, Saint Paul, upon his return from post graduate study in Vienna in November, opened an office for general practice at 1035 Lowry Medical Arts Building.

Dr. Hugh Cabot, dean of the Medical School of the University of Michigan since 1921, will become Senior Consultant in Surgery at the Mayo Clinic, June first. Dr. Cabot was formerly professor of surgery at the Harvard Medical School.

Dr. Kano Ikeda took charge of the laboratories at the Charles T. Miller Hospital, Saint Paul, the first of the year, when he severed his connections with St. Luke's Hospital. He had been pathologist at St. Luke's Hospital for more than three years.

Dr. Harold Stratte, class of 1920, University of Minnesota, formerly of Hallock, Minnesota, has become associated with Dr. L. Sogge at Windom. Dr. Ellsworth Johnson of Windom begins a fellowship in radiology at the Mayo Clinic, April first. He formerly was associated with Dr. Sogge.

Dr. A. E. Flagstad, who until recently was associated with Drs. Chatterton and Von der Weyer, was recently appointed Deputy Coroner in Minneapolis. He maintains offices at 1549 Medical Arts Building, Minneapolis, and at 218 Lowry Medical Arts Building, in Saint Paul, for the practice of orthopedics.

Dr. Tressa Moran assumed charge of the laboratories at St. Luke's Hospital, Saint Paul, March first, coming to Saint Paul from Waterloo, Iowa. Dr. Moran received her medical degree at the Loyola Medical School, Chicago, and for a time was at the Mercy Hospital at Iowa City, and later pathologist and X-ray supervisor at the Allen Memorial Hospital, Waterloo, Iowa.

The fourth annual prize of $250.00 will be awarded this year by the Minnesota Society of Internal Medicine to the practicing Minnesota physician, not a member of the Society, who is deemed most worthy to receive a prize in research in clinical medicine. Inquiries and theses should be submitted to the Chairman of the Committee, Dr. E. T. F. Richards, Hamm Building, Saint Paul, before October 1, 1930.

The International Medical Club was formed in New York City a few years ago in order to promote contact between the graduates of foreign medical schools residing in this country and American medicine. Foreign language medical societies in New York City include a Spanish, German, Russian, Hungarian, Greek, Celtic and two Italian societies. Heretofore there has been no relationship between them. This item is published so that foreign medical graduates or American physicians interested may join the club. Dr. Richard Kovacs, 223 East 68th Street, New York City, is secretary.

EFEDRON HART NASAL JELLY

EfeDronN Hart Nasal Jelly is another one of the ever increasing ephedrine proprietaries. The preparation is made by the Hart Drug Corporation, Miami, Florida. According to the label the formula is: Ephedrine hydrochloride Gr. 1; Chlorbutanol Gr. 2 1/4; Sodium Chloride Gr. 2 1/4; Menthol Gr. 3; Phenol Gr. 2; Oil of cinnamon Gr. 0.08; Jelly base q. s. ad drachms 5. The preparation has not been accepted for New and Nonofficial Remedies. While physicians' samples of this product have been liberally distributed, the carton is one which seemingly is addressed to the public as well. (Jour. A.M.A., February 8, 1930, p. 430.)

ANTISTREPTOCOCCUS SERUM OMITTED FROM N.N.R.

The Council on Pharmacy and Chemistry reports that for some years it has been questioning the value of antistreptococcus serum preparations. In 1928 the Council decided that unless new and favorable evidence became available, all streptococcus serum preparations would be omitted from New and Nonofficial Remedies with the close of 1929. Since no such new evidence has become available, the Council has omitted all antistreptococcus serum preparations as follows: Antistreptococcic Serum (Gilliland Laboratories, Inc.); Antistreptococcic Serum, Polyvalent (Lederle Antitoxin Laboratories); Antistreptococcic Serum (Eli Lilly & Co.); Antistreptococcic Serum, Purified and Concentrated (Lilly); Antistreptococcic Serum, Polyvalent (H. K. Mulford Co.); Antistreptococcic Serum (National Drug Co.); Antistreptococcic Serum (Parke, Davis & Co.); Antistreptococcic Serum-Squibb. (Jour. A.M.A., February 15, 1930, p. 484.)

CONSULTATION BUREAU

Wm. A. O'Brien, M.D., *Director*
Minnesota State Medical Association
11 West Summit Avenue
Saint Paul, Minnesota

1. *Question.*—Please explain the technic used in convalescent serum prophylaxis for measles.

Answer.—Withdraw from 10 to 100 c.c. of blood, depending upon the condition of the donor, the fifth day the measles patient is afebrile. Centrifuge the blood, separate the serum from the clot, and keep the serum in an icebox. The serum is said to last up to two years, although this is doubtful. Citrated blood may be used if the blood is not to be kept too long.

If passive immunity is desired, make one injection of serum into the anterior thigh muscles five days after exposure. From seven to twelve c.c. are used, depending upon the age of the patient. If you wish to take advantage of the patient's own production of antibodies and run the risk of producing a mild or modified measles with more lasting immunity, the injection is made on the tenth day after exposure.

The indications are institutional practice, epidemic of virulent measles and protection of exposed children in a family which has come in contact with measles. This is often done when the exposed children are not well.

2. *Question.*—What is the most likely diagnosis and treatment for our patient who has the following history: Female, 54, married, came to us for examination because of severe backache and pain radiating down the right thigh to the knee with some weakness in the right lower extremity. Severe backache has been present for the past six or seven weeks and the pain in the thigh for about four weeks. She also complained of neuralgia in the right side of her neck, which extends from the ear down to the front of her neck. She had lost some weight but did not know how much. Mother died of cancer at seventy-five. Patient's gall-bladder was removed about seven years ago. Has had severe backache at intervals since then. Four years ago she was seen by a physician because of the backache. An *x*-ray examination was reported as negative, and she was given a brace. She has had seven children, with no difficulty during pregnancy or delivery. Passed the climacteric three years ago. There has been no history of any pelvic disorder. When first seen, physical examination was negative except for definite tenderness along the right sciatic nerve from the hip to the knee. Hyperextension caused moderate pain, and there was also a definite tenderness of the right sacroiliac joint. She looked rather pale, and there was evidence of weight loss. Blood pressure 125/75. A tentative diagnosis of sciatic neuritis was made, and she was sent to the hospital for observation and treatment.

Since that time the pain has become more severe and is now bilateral. She has developed a prominence in the region of the eleventh and twelfth thoracic vertebræ. She had also developed a mass over the upper sternum, which has reached the size of a small orange. It is quite firm and apparently arises from the bone, as it is firmly fixed to it. Pelvic examination shows some tenderness under the abdominal wall in the midline. Laboratory: hemoglobin 84 per cent (Sahli), erythrocyte count 4,300,000, leukocyte count 3,900. Urine shows a few pus cells; red cells have never been present. X-ray examination shows a destructive lesion in the tenth thoracic, first, second, and third lumbar bodies, a mass in the mediastinum, and elevation of both sides of the diaphragm.

Answer.—Differential diagnosis is between Hodgkin's disease and metastatic carcinoma. Ewing's tumor (endothelioma) should also be considered as it involves bone, lymph nodes, and viscera. An absolute differential diagnosis can be made by excising the small piece of tissue from the sternal tumor. A search should also be made for a possible primary carcinoma. Sometimes a very small breast tumor will give metastases such as you have described. In any event, deep *x*-ray treatments should be given if the patient's condition justifies it. These treatments will probably relieve the pain and temporarily halt the progress of the disease, but the outcome will probably be lethal.

3. *Question.*—I have a patient, a seventeen year old boy, who hurt his knee two weeks ago while playing basketball. He states that he "did not come down right on the knee." Pain following the injury was only slight and the swelling not very great. He has been unable to completely extend the leg, and up to the present time has shown no improvement. X-ray plates show a partial separation of the spine of the tibia. Will you please advise me as to the diagnosis and treatment of this condition, as I have been unable to find anything about it in my textbooks.

Answer.—The most probable diagnosis is a shearing injury of the spines of the tibia. A search should be made for previous disease or injury in the bone. Tuberculosis is also another possibility, but it probably can be ruled out from your history and description of the lesion. Another possibility should be considered; that is, that the lesion is an old one and that the recent injury either aggravated it or brought it to the attention of the patient. Laceration of the crucial ligaments usually accompanies this form of trauma. An attempt should be made to find out if there is any displacement of the tibia. Grasp the leg above and below the knee and try to elicit displacement. Forward displacement will probably indicate that the posterior ligament is involved while posterior displacement usually points to involvement of the anterior ligament. Please let us know if displacement is present, and we will advise you as to the future treatment. If no displacement is present, conservative treatment will probably be all that is needed.

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of February 19, 1930

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, February 19, 1930, having been postponed one week on account of the meeting of the American College of Physicians. Dinner was served at 7 p. m. and the meeting was called to order at 8 p. m. by the President, Dr. Emil S. Geist. There were 38 members and 1 visitor present.

Minutes of the January meeting were read and approved. A Committee consisting of Drs. Freeman, Foley, and S. E. Sweitzer was appointed by the President to draw up a memorial of Dr. Paul B. Cook.

The scientific program of the evening consisted of two theses and a case report, as follows:

Dr. Albert G. Schulze, St. Paul, read his thesis entitled "A Plea for the Radical Treatment of Incomplete Abortion."

DISCUSSION

Dr. John F. Noble (St. Paul) (by invitation): The curettings from the cases which Dr. Schulze has described were sent to the Ancker Hospital Laboratory for examination. They were described grossly and microscopically and this decription was filed with the charts. The data which he has cited was taken from these reports. No clinical histories were available with the specimens so that, in the few cases where a diagnosis of acute or chronic endometritis was made, only endometrium was found in the specimens and this endometrium contained acute or chronic inflammatory cells with no products of conception present to confirm the clinical diagnosis of incomplete abortion.

I do not believe that the division of these cases into two groups, clean and infected, on the basis of the presence or absence of inflammatory cells is sound. The very nature of incomplete abortion makes the presence of necrotic tissue a common finding and the necrotic material sets up an inflammatory reaction in the uterus which cannot be separated microscopically from bacterial inflammation, and in those instances where large amounts of material were removed from the uterus, only small blocks of tissue were examined and other areas might have shown leukocytes. I think my reports have misled Dr. Schulze in this matter.

Practically the only method by which a pathologist can judge the value of a therapeutic measure of this type is by the mortality rate. The fact that Dr. Schulze has treated 235 consecutive cases without a death speaks for itself. When I went to the Ancker Hospital about five years ago and these specimens began to appear in the laboratory, I fully expected to be called upon to autopsy some of them, but as time went on and no deaths occurred, I came to the conclusion that at least in his hands it was a satisfactory method of treatment.

From a pathological standpoint, there are two things to consider when a curettage of an incomplete abortion is contemplated. In the first place a curette is bound to break down the natural defensive reaction in the uterine wall against infection, and to open up channels for infection, but in thoroughly removing necrotic tissue which is an excellent culture media, the danger of infection is reduced. This is undoubtedly desirable. The question then is simply: What is the least harmful method of removing placental and decidual remnants from the uterus?

I would like to ask Dr. Schulze whether or not any of these cases were criminal abortions.

Dr. J. L. Rothrock (St. Paul): I was very much interested in Dr. Schulze's paper, especially his plan of treatment.

I had hoped he would say something about abortion in the various stages of pregnancy up to four months. It seems he evidently has dealt principally with abortions of early pregnancy. We are liable to fall into error in attempting to apply a stereotyped plan of treatment to all cases, and here, as elsewhere, I believe it a safer plan to meet indications existing.

I, too, have had a considerable experience in the treatment of incomplete abortions. Formerly, two or more decades ago, it was the almost universal practice decided that the abortion was inevitable. In applying this plan indiscriminately to all manner of cases, unpleasant consequences sometimes followed, especially in infected cases, and it is not always possible to tell in advance whether infection is present or not. For that reason I have long since adopted more conservative measures. My plan of treatment was usually this: If the abortion seemed inevitable, and the cervix was undilated, and if considerable hemorrhage was taking place, a gauze pack was firmly placed in the vaginal vault around the cervix and the patient was then given quinin or ergot and, in many instances, within 8 to 12 hours on removal of the pack, the contents of the uterus would be expelled or be protruding from the dilated cervix and could easily be removed with a forceps without invading the uterine cavity. If not, the cervix would be found sufficiently dilated to admit a finger and the uterine cavity could be explored and any adherent or retained membranes could easily be removed, often without any anesthetic. Other cases, which, on account of hemorrhage, demanded prompt relief, were of course curetted.

I think the objections and difficulties, mentioned by Dr. Schulze, to digital removal of retained portions of placenta and membranes are theoretical and in my experience have not been met. My experience in this respect has been identical with Dr. Williams', so admirably expressed in his textbook.

One of the surprising things in early abortion is the comparative freedom from fatality on account of hemorrhage; I have never known a case of fatal hemorrhage in an early abortion, and Hofmeier quotes Alfred Hegar as stating that in more than 40 years' experience he could recall no case that died from hemorrhage following abortion in early pregnancy. In the recommendation of the curette, its dangers must not be lost sight of. If the uterus is soft, it is easily perforated, perhaps without much risk to the patient, but

still a potential risk. A too thorough curettage of the recently pregnant uterus may remove so much of the endometrium that scars are left and if the patient becomes pregnant again there may be an adherent placenta.

Furthermore, the curette is not so certain a method of removing all of the placental tissue. To be convinced of this one has only to make a digital examination following a curettage to note how much placental tissue has been left behind. Another disadvantage of curettage is that the curette stimulates the normal rhythmic contraction of the uterus to an exaggerated degree and my experience has been the loss of much more blood during curettage than where the placenta is removed with the finger.

The general consensus of opinion is that the curette may be dangerous in infected cases, causing a rapid extension by opening up new avenues favoring extension.

The highly favorable outcome in this series is undoubtedly due in a large measure to Dr. Schulze's skill in the use of the curette, but the thought occurs to me that in this series he was dealing almost entirely with uninfected cases, or at least not with hemolytic streptococcus infections.

Dr. Arnold Schwyzer (St. Paul): Dr. Schulze has had excellent results. However, he made the statement at the end of the paper that the use of a sharp curette is a safe procedure. I don't think that it is right to make such a broad statement to be followed by every practitioner. I will refer to one case I saw when still an assistant in the Women's Hospital of Zurich. The chief assistant was curetting a woman and I was assisting him. He got out a lot of material, a lot of white bands, and it seemed queer that so much material could come out. I then remarked to him, "This is muscle." He had scraped out much of the uterine muscular tissue. She had fierce bleeding and was packed. When the packing was removed in about two days, the bleeding started again and we had to pack again, and after this a third time. Then the case seemed all right. But what happened later on I do not know. So, if one says that a sharp curette is a safe thing, this is stating too much. In skilled hands like Dr. Schulze's he has shown that it is all right; but to give that out as holding good for every doctor, is a dangerous thing. Furthermore, I don't think it is often necessary to insert the whole hand into the vagina to palpate the uterine cavity with one finger as Dr. Schulze stated. A sharp curette, especially in the later months, can do a great deal of damage. You do not need to get every shred at once; small particles will come away with the packing.

I would like to say here that a good number of years ago Professor Chlumsky published a paper in which he told of the value of a phenol-camphor mixture. When carbolic acid crystals and camphor crystals are put together they melt into a clear fluid. He used 30 per cent of carbolic acid and 60 per cent camphor, and the rest alcohol to make up 100. This is an exceedingly strong, non-cauterizing, antiseptic solution, and we moisten the gauze with this. You can leave it in for three days and it comes out still smelling sweet.

To return to the objection I raised: With a sharp instrument you might curette out the muscular coat; if not careful this possibility should be reckoned with. If we never had heard of this danger and did not watch what we scrape out, we would be liable to do much damage even if we do not perforate the uterus.

Dr. H. B. Sweetser (Minneapolis): While listening to Dr. Schulze's paper, I said to myself, "In the hands of an expert, like Dr. Schulze, possibly it is safe to use a sharp curette, but in the hands of the general practitioner, to whom many of these cases come, both in hospitals and in homes, I feel sure that such a procedure will result in disaster if not a few cases."

Twice, in my experience, I have had to resect coils of bowel which were pulled down through a perforation of the uterus under the mistaken impression that they were secundines. The wall of the pregnant or recently pregnant uterus is very soft and relaxed, and it requires a very educated tactile sensibility, especially when applied through a sharp curette, to determine that the curette is gliding along the wall and not through it. Therefore, I think it would be a dangerous thing to send out a report of this kind, showing such good results in the hands of an expert.

Dr. H. T. Nippert (St. Paul): When I started out as a country practitioner in St. Paul about 37 years ago when you could not get a patient to a hospital, I had more abortions than confinements the first few years. I used to go in, but not with a sharp curette. I used a dull curette and would clean out as much as I could and then went in with the finger and frequently had to go in again as I found after digital examination there were still some pieces of placental tissue or membranes left. A great many I emptied with only the index finger. One case especially comes to my mind. I had put the patient across the bed and soaked a few towels in bichloride of mercury solution and put over her abdomen and thighs. When I was curetting her the curette suddenly went in up to the handle and I said "that has gone through the uterus." On each visit afterwards I was afraid something would show up but nothing did. I feel like Dr. Schwyzer, if a woman is pregnant three or four months, I would wait and see what happened but if early in pregnancy I would go in with a dull curette. I have never seen any mishap nor had any bad results from it. Now things are done much more simply and antiseptically in the hospital. Even in private homes I would do it with the dull curette and think we would get along just as well.

Dr. R. T. LaVake (Minneapolis): The importance of this subject demands a full and free discussion. My experience leads me to practice and advocate the conservative treatment of incomplete abortions. A survey of literature leads me to believe that it is the opinion of the great majority that the conservative treatment is the treatment of choice.

Dr. Schulze has outlined in his interesting paper his reasons for having changed from his advocacy of conservative treatment to his advocacy of radical treatment with the sharp curette. It is instructive, but quite

disturbing to any positive attitude of assurance on any subject, to contemplate the widely different conclusions that can be drawn from the same cold facts and figures. To my mind, the facts and figures in Dr. Schulze's stimulating paper show what can be done with a sharp curette and not what should be done or advocated.

Conservative treatment of this condition implies noninterference except upon the indication of profound or protracted bleeding, or for the possible drainage of pus collections. In private practice most abortions are not induced and in these cases my experience convinces me that 9 out of 10 are so complete that routine intervention of any kind may be classed as meddlesome and unnecessary. In a general hospital a greater percentage of abortions prove to have been induced and a greater percentage will need interferenc at some period in their treatment. This is a point that I did not hear mentioned in this paper.

When profuse or extended bleeding points to the possible advisability of interference, to my mind each abortion should be considered as potentially infected until one can be reasonably sure that it is not, by the temperature, leukocyte and differential counts and, possibly, by the sedimentation test if doubt still prevails. Temperature alone, as a criterion of safety, is not sufficient. If it is an infected case, one can visualize the infected area as surrounded by a protective leukocytic barrier that must not be broken down, if avoidable, by any form of intervention. In any case, when intervention is definitely indicated, I deem the finger to be the safest instrument. If the finger proves to be inadequate, the next safest instrument is the largest dull curette that can be inserted. Even this should be used with the greatest caution. The larger the curette, the less likely is the danger of perforation. Although many of us have been lucky enough not to have perforated a uterus with a curette, most of see at least one perforation a year, and our turn is to be expected. Very few men of large experience have not perforated a uterus.

In my opinion the sharp curette should be used mostly as a diagnostic instrument, and should be used as a curative agent only when infection has been as nearly definitely excluded as possible and when the condition is found to be other than an incomplete abortion. Even then the sharp curette is not without danger, as I have learned from bitter experience in cases where, under the best conditions of surroundings, supervision and technic, the most alarming results of infection have followed a simple diagnostic curettage.

From the standpoint of relative safety, the number of days one should wait before intervention after the temperature, leukocyte count and sedimentation test have been normal, no one so far as I know can state with any degree of assurance. Personally I would rather have an interval of over a week than under a week, if the scant loss of blood warrants the delay.

Dr. Frank Wright (Minneapolis): I would like to ask how a man is to become expert in the use of the sharp curette if he does not begin to use it until he is expert.

Dr. C. M. Carlaw (Minneapolis): Why use the curette at all? In the early 90's at the old Asbury Hospital I curetted one of these cases with a sharp curette and the first think I knew I was tickling the umbilicus. I became very much alarmed and when I saw Dr. Dunsmoor in the hall outside of the operating room I told him what I had done. He said that so long as I did not pull down a loop of intestine it was all right. That case did teach me not to use the sharp curette. I think in most cases that need curetting, completing the dilatation with a Goodell dilator and working with a sponge holder you can with safety empty the uterus and then instead of the curette, roll gauze around a uterine forcep and with this, curette the inside of the uterus by rotating it around in a corkscrew action. You will be surprised how easily and thoroughly you can polish the inside of the uterus with this sponge curette. Follow this cleaning by swabbing out the uterine cavity with Skene's solution of iodin and then clean up the parts with alcohol. You will find the bleeding will stop, the uterus will contract, the temperature will drop and the patient will rapidly get well.

Dr. J. F. Hammond (St. Paul): I think the discussion about the curette can be applied to any instrument. The scalpel is a very dangerous instrument if not used properly. I think the curette can be put in the same class. In the majority of cases, particularly in abortions before the third month, the simplest way to empty the uterus is with the curette. I quite agree with what the speaker has said about infection. I was brought up on the radical treatment, if you wish to call it that, and in the maternity hospital where I was in 1906-07 our attempt was to empty every uterus as quickly as possible. At that time Williams was preaching the use of the finger. If one or two fingers could not be inserted through the cervix we were told to incise the cervix, but that always seemed to me to be a radical procedure. As a matter of fact we never carried that out. The difficulty I had with the use of the finger was that I could not be sure that I was removing everything. So I think in early abortion, where you have decided there are no contra-indications and no infection going on, the uterus can be emptied in a conservative way by using the curette. I don't think one need use a sharp curette. It is very easy to put any curette through the uterus. Dr. Nippert's remarks remind me of Dr. Chipman, who always impressed on the students the necessity of care in the use of the curette. He once asked one of the students what he would do if the curette went through the uterus. The student said he would pull it back.

Dr. LaVake said that, if you wait, 9 out of 10 will not need any interference. That is true, but they will have a very long convalescence. After the first 3 or 4 months I think the simplest way to do is to pack the cervix and allow the uterus to expel the contents. As Dr. Rothrock has said, you will likely find the ovum in the vagina in 48 hours. In infected cases I think it is well to wait until the temperature is normal. There is another class of cases where it is urgently necessary to interfere—where the patient is bleeding and infected.

I have had two cases where that condition existed. They were losing a lot of blood and were definitely infected. The question arose as to what would be conservative treatment. In those two cases I felt that the safer way would be to do a hysterectomy and I did it. That can be condemned too and it has been done, but those two cases recovered. One has to be up against a case before he can decide just what to do. I think Dr. Schulze's management of these cases has been very good. I had previously thought he followed or advocated never touching the uterus in these cases but I see he does not believe in allowing his cases to go on indefinitely.

Dr. Schulze (in closing): I do not wish to create the impression that I curette everything. All of this work was done in my service at the Ancker Hospital where we are obliged to take whatever comes.

There are three groups of cases where we follow a waiting policy. The first group include those women generally three months pregnant or more who very likely have had a complete miscarriage instead of incomplete. We give them the benefit of the doubt and our further treatment is dependent on their clinical course. The second group include those women who are running a temperature. Here we are obliged to wait, as such a patient is not a good surgical risk. The third group include those women who, although they have no temperature, have been criminally aborted. These women are potentially infected. It is always permissible to remove plugs of placental tissue from the cervix.

Dr. Noble asked if any of these were cases of criminal abortions. To this I would reply that my estimate would be that about one-third of them are.

Dr. Rothrock inquired about the stage of pregnancy. The majority of these cases were in the first trimester. We had one case which proved fatal from the anemia following the tremendous loss of blood, but this case was not curetted.

Dr. LaVake stated the facts very aptly when he said that each man follows the method which he likes best and my preference in the matter is set forth in my paper. It is difficult to state who has become skilled in curetting a uterus, but any one who undertakes it should be careful. Dr. LaVake's choice is one of noninterference because he feels that by waiting his patients will not require interference; but other factors must be considered. How long do these patients bleed? How much do they bleed? How long are they in the hospital? Are you not exposing these patients to possible infection? I am guided by my results, which I feel have been very good.

Dr. Martin Nordland (Minneapolis) read his thesis entitled "The Larynx as Related to Surgery of the Thyroid, Based on an Anatomical Study." Numerous lantern slides were shown.

DISCUSSION

Dr. Gustav Schwyzer (Minneapolis): Even if a surgeon doing thyroidectomies cannot regard all the finer ramifications of the nerves, nevertheless it is very important and imperative that he knows the exact course of the nerves in his field of operation.

Dr. Nordland has shown us a number of beautiful pictures reproducing anatomical dissections he has done recently at the University of Minnesota. His work concerns in particular the superior and inferior (recurrent) laryngeal nerves. Both are cervical branches of the vagus. The vagus itself coming from the brain through the foramen jugulare forms a thickening shortly after leaving the skull and this is called the ganglion nodosum. This ganglion receives motoric fibers from the 11th and 12th cerebral nerves, the accessorius and the hypoglossus. Thus we have in this ganglion sensory and motoric fibres. That the superior laryngeal nerve in its external branch carries motoric fibers has been known to us for a long time. We know that the cricothyroid muscle, a muscle which is destined to tense the vocal cords, and the pharyngeal inferior constrictor muscle are innervated by the external branch of the superior laryngeal nerve. The pharyngeal muscles are playing an important part in the phonation.

The very special points that Dr. Nordland brings out concern the internal ramus of the superior laryngeal nerve. In a beautiful specimen of a resected larynx he shows us that a number of branches of this internal ramus of the superior laryngeal nerve goes into the interarytenoid muscle. This work corroborates the work of others.

For years we have practiced a method of ligating the entire upper horn instead of only the blood vessel running into the same. This procedure undoubtedly safeguards the superior laryngeal nerve and avoids paralysis of the cricothyroid muscle. In spite of this method, however, I remember we had cases of temporary hoarseness, the phenomenon explained here tonight. The condition just brought to our attention should not be confused with a paralysis of the vocal cords by injury to the recurrent nerve.

DeQuervain's method of ligating the inferior thyroid artery is of decided advantage. It ligates this artery at its trunk and not only one of its branches. It causes remarkable hemostasis which is striking in bleeding toxic goiters, and finally it means the safety of the recurrent laryngeal nerve, because the ligation takes place quite a bit farther out at the point where the inferior thyroid artery comes and makes a curve from beneath the common carotid.

In cases of recurring goiter, particularly in toxic goiter where we have to operate again, it is my belief that the method of ligating the inferior artery as mentioned above is liable to bring on injury to the recurrent laryngeal nerve because of the distorted anatomy. For this reason I do not consider this procedure a very safe method when operating on recurring goiter cases.

I wish to thank Dr. Nordland in the name of Academy for his interesting pictures of the anatomical dissections he has shown us tonight.

Dr. A. E. Benjamin (Minneapolis): I am pleased to have seen this presentation. It gives us a more vivid idea of the arterial, venous and nerve supply of the thyroid area. A number of years ago I did some dissecting in this region to determine what was the best

procedure in thyroid surgery, and after witnessing operations in various parts of the United States and Europe, I decided that thyroid surgery had been made too difficult and with too much effort on the part of the operator. I then began more or less mass control by using the clamp, endeavoring to clamp the blood vessels and capsule of the upper pole and the gland tissue below, including the branches of the inferior thyroid. I then found that thyroid surgery was very easy in the majority of cases because the hemostasis was almost perfect. I always use plain catgut. I had no trouble, no hoarseness resulting, and so far have not included any nerve structure, although that may have been good luck. At any rate, this plan has obviated any of the unfortunate results in the work. I found it unnecessary to ligate every branch but dissected out the diseased portions of the lobes, then passed the sutures back and forth through the capsule and any of the gland that was left. In this way I then had a pretty clean field all the time. It has been very satisfactory. I have not yet had the boldness in many cases to ligate the artery beyond the fascia, thinking perhaps it might be that, if I disturbed the blood supply of the remaining gland tissue too much, I might have some unfortunate results.

Dr. H. A. H. Bouman (Minneapolis): I rise to say that I have listened to Dr. Nordland's thesis not only with profit but with great pleasure and a feeling of gratitude, having known him when he was a very young man in our section of the city.

Some microscopical studies have also been made of late to determine the nature of these nerves. The vagus is not a compact cable, but is composed of numerous bundles held loosely together by connective tissue. On cross section in the neck region various kinds of fibers are seen. Some have heavy, some delicate medullary sheaths and fewer are bare axis cylinders. The laryngei carry by far the most fibers with heavy sheaths; indeed, the recurres seems to be made up almost entirely of these fibers, which are motor.

Regarding the ligature of the inferior thyroid, Kocher taught to tie this vessel at exactly the same place, but he did not separate the muscles to reach it before exposing the goiter, as Dr. Nordland has practiced.

Dr. Nordland (in closing): I want to thank the gentlemen for their discussion of my paper. I have nothing of importance to add. I did not intend to discuss the various advantages of the ligature of the inferior thyroid artery, according to deQuervain. The point I want to stress is that it is occasionally necessary to ligate this vessel, and, when it is, I believe the anatomical factors indicate that it is an advantage to ligate it according to this method.

Dr. A. R. Hall (St. Paul) gave a report of "Abnormal Subclavian Arteries" and showed *x*-ray films. (To be reported later.)

The meeting adjourned.

R. T. LaVake, M.D.,
Secretary.

NEW AND NON-OFFICIAL REMEDIES

The following article has been accepted by the Council on Pharmacy and Chemistry.

United States Standard Products Co.

Diphtheria Toxin-Antitoxin Mixture 0.1 L+ (Non-Sensitizing) Prepared from Sheep Serum.

The following articles have been exampted and included with the List of Exempted Medicinal Articles (New and Non-official Remedies, 1929, p. 481):

Robert McNeil

Tincture Digitalis Duo-Test McNeil

Black Capsules Digitalis Duo-Test McNeil

TRUTH ABOUT MEDICINES

Meads Viosterol In Oil 100 D.—A brand of viosterol in oil 100 D, N.N.R. (Jour. A. M. A., August 31, 1929, p. 693). Mead Johnson & Co., Evansville, Ind.

Lenigallol-Zinc Ointment. — It contains lenigallol (Jour. A. M. A., April 6, 1929, p. 1181) 6 per cent in a base composed of zinc oxide ointment-U.S.P. E. Bilhuber, Inc., New York.

Typho - Serobacterin - Mulford (Sensitized Typhoid Vaccine) (New and Non-official Remedies, 1929, p. 384).—This product is also marketed in packages of three syringes, being three immunizing doses. H. K. Mulford Co., Philadelphia. (Jour. A. M. A., February 1, 1930, p. 339).

FOODS

The following products have been accepted as conforming to the rules of the Committee on Foods of the Council on Pharmacy and Chemistry of the American Medical Association. These products are approved for advertising in the publications of the American Medical Association, and for general promulgation to the public.

Junket (The Junket Folks, Chr. Hansen's Laboratory, Inc., Little Falls, N. Y.).—To prepare the product the dried blown or dried salted rennets in ordinary salt brine is extracted. The enzyme is then precipitated by salting the saturation and the resulting precipitate is mixed with pure Worcester salt, dried and pressed into tablets. Flavored Junket consists of rennet powder, similar to that used for Junket Tablets, except that this is mixed with cane sugar and natural flavoring. While the rennin enzyme itself does not add to the fuel value of milk, it makes it more wholesome because of its digestive action on the milk.

Spintrate (Spinach Concentrate) (Spinach Products Co., Inc., Norfolk, Va.).—Spinach in the form of a fine powder made from fresh spinach of the Savoy or curly leaf type. Spintrate is an excellent source of food iron, calcium, and phosphorus; it is also a rich source of vitamin A, B (B_1) and G (B_2).

Whitefield Genuine Grapefruit Juice (Whitefield Citrus Corporation, Long Island City, N. Y.).—This is pure undiluted juice of sun-ripened grapefruit and contains no added preservatives. The process of manufacture preserves the original character of the juice.

Whitefield Genuine Orange Butter (Whitefield Citrus

Corporation, Long Island City, N. Y.).—This is an orange preserve with a new and different flavor and consistency made from tree-ripened fruit.

Aunt Jemima Pancake Flour (The Quaker Oats Co., Chicago).—The product is a mixture of four flours—wheat, corn, rye, rice—with sugar, milk, baking powder and salt.

Aunt Jemima Buckwheat, Corn and Wheat Flour (The Quaker Oats Co., Chicago).—This is a buckwheat corn and wheat flour.

Quaker Crackels (The Quaker Oats Co., Chicago).—This is composed of corn, wheat and oats.

Quaker Quick Macaroni (The Quaker Oats Co., Chicago).—This is a new-type macaroni. A milk containing macaroni that cooks in five minutes instead of twenty. (Jour. A. M. A., February 8, 1930, p. 411).

Bordens Evaporated Milk (The Borden Co., New York City).—It has the following average composition: fat, 7.85%; protein, 6.88%; carbohydrates, 9.67%; ash, 1.55%; total solids, 25.95%; water, 74.05%. The product is manufactured from whole milk. Borden's Evaporated Milk is advertised for infant feeding and for household use in making milk convenient for cooking. It is claimed that the milk is clean and sterile; that it resembles breast milk in ease of digestion; and that it produces fine flocculent curds.

Cream of Wheat (Cream of Wheat Co., Minneapolis).—It is a product made entirely from wheat. It consists of the endosperm of the wheat, with only so much of the bran and germ as it is impossible to remove. The product is used because it is rich in energy content and easily digested.

Gerber's Strained Vegetable Products (Gerber Products Division, Fremont Canning Co., Fremont, Mich.).—Brands: Gerber's Strained Spinach, Strained Carrots, Strained Green Beans, Strained Peas, Strained Prunes, Strained Tomatoes and Strained Vegetable Soup. Specially selected vegetables, steam pressure cooked and sterilized at high temperature. It is claimed that by excluding air and cooking under steam pressure without water, a greater conservation of mineral salts and vitamin elements is effected.

The New Pettijohn's (The Quaker Oats Co., Chicago).—This product consists of the whole wheat grain. It is obtained by steaming and flaking wheat which has a tender bran, the bran being included in unground form. The product contains all the nutritive elements of whole wheat.

Post's Bran Flakes with other parts of Wheat (Postum Co., Inc., Battle Creek, Mich.).—The product is composed of bran flakes with other parts of wheat, flavored with malt syrup and salt. It combines the advantages of wheat bran in a nourishing and appetizing food. (Jour. A. M. A., February 15, 1930, p. 485.)

Muffets (Irradiated) (The Quaker Oats Co., Chicago).—Whole wheat, cooked, crushed, drawn out to filmy ribbon of wheaten threads. Wound round and round, baked and toasted. Muffets (Irradiated) makes vitamin D available in a breakfast food for all ages except infants. It is not intended as a therapeutic agent to supplant cod liver oil.

Quaker Farina (Irradiated) (The Quaker Oats Co., Chicago).—Farina passed under the rays of ultraviolet lamps until it acquires vitamin D. The product will improve calcium and phosphorus retention. It holds its irradiation under extreme conditions of cooking and storing.

Quaker Puffed Rice (The Quaker Oats Co., Chicago).—This product consists of rice kernels puffed to eight times normal size, providing for easy assimilation and retaining important food elements.

Quaker Milk Spaghetti (The Quaker Oats Co., Chicago).—The product is made from whole milk and wheat. (Jour. A. M. A., February 22, 1930, p. 559).

PROGRESS

Abstracts to be submitted to Section Supervisors.

Members are urged to abstract valuable articles which they run across in their reading and send the abstracts to the physicians in charge of the respective sections. In order to avoid duplication it would be well to communicate with one of the section supervisors before the article is abstracted.

TUBERCULOSIS IN PUBLIC SCHOOL CHILDREN: Opie, H. R. Landis, McPhedran and Hetherington (Amer. Rev. of Tuberc., 1929, XX, 413). Sanatorium treatment gives children with manifest tuberculosis the best chance for recovery.

A certain number of children acquire serious tuberculous infection unaccompanied by physical signs or symptoms which, unless checked, will become clinical tuberculosis.

In the present study an attempt is made to apply the knowledge of latent tuberculosis that has been acquired by investigation of the spread of tuberculosis in families to the recognition and control of tuberculosis in schools.

About 800 white pupils and about 800 colored pupils in Philadelphia schools were studied.

To detect advanced latent tuberculosis, the tuberculin reaction and *x*-ray examinations were found useful. A history of contact with tuberculosis was often difficult to obtain.

The following are some of the types of advanced

latent tuberculous infection found: 1. Tuberculosis of tracheobronchial lymph nodes. 2. Tuberculous infiltration of the lung, of the childhood type. 3. Apical lesions of the adult type occurring in children, 12 to 18 years of age. The tuberculin test performed on 4,000 children showed that tuberculous infection is now scarcely less frequent in Philadelphia than in the cities of Europe 20 years ago.

Severe infiltrating lesions were remarkably prevalent in adolescent girls.

Manifest disease was found four times as often in adolescent colored children as in white children of the same age.

Prophylactic care controlled by repeated physical and roentgenological examinations furnishes a means by which advanced latent infection may be arrested before it has developed into clinically manifest disease. Children with the following conditions should receive special care in nutrition-tuberculosis classes or by some other regimen adapted to their needs, and they are suitable for admission to a preventorium if it is available:

(1) Manifest pulmonary tuberculosis with no symptoms, physical signs or roentgenological evidence indicating that the lesion is active. Sputum, if present, must be demonstrated to be free from tubercle bacilli.

(2) Latent apical tuberculosis.

(3) Latent tuberculous infiltration of the lung often associated with tuberculosis of tracheobronchial lymph nodes. In some instances, particularly in older children, these lesions are the scars of preëxisting infection.

(4) Tuberculosis of tracheobronchial lymph nodes, even though partly calcified (a) when the child is still in contact with open tuberculosis; (b) when the reaction to tuberculin is unusually intense; (c) when the lesions are unusually large or very numerous; (d) when they are associated with evidence of impaired health perhaps not referable to tuberculosis and including advanced underweight.

The study of the contagion of tuberculosis in families exposed to open tuberculosis has shown that children with the lesions just described are liable to develop manifest disease, but it is not assumed that the foregoing groups include all of the children who will develop manifest tuberculosis.

The following types of tuberculous infection are widely prevalent among healthy children and do not require special care:

(1) Infection demonstrated by a positive tuberculin reaction without lesion demonstrable by roentgenological examination even though there is contact with open tuberculosis. (Repeated examination are, however, essential for all children in contact with open tuberculosis.)

(2) Circumscribed nodules in the lung substance that have undergone calcification.

(3) Roentgenologically demonstrable tuberculosis of tracheobronchial lymph nodes that are partly calcified, except under the conditions outlined above. Sharply defined, very opaque lesions are likely to be healed or healing.

SURGERY

SUPERVISORS:
DONALD K. BACON,
LOWRY BLDG., ST. PAUL
VERNE C. HUNT,
MAYO CLINIC, ROCHESTER

PRIMARY CARCINOMA OF THE URETER—REPORT OF A CASE AND A REVIEW OF THE LITERATURE: Louis M. Rousselot and John Daniel Lamon (Surg., Gynec. and Obstet., Vol. L., Jan., 1930, No. 1, 17-28). Rayer is given credit for having described the first case of this rare disease in 1841. Blatt collected forty cases from the literature in 1926. The authors review forty-eight cases collected from the literature and add a case report of their own, bringing the total up to forty-nine.

Men and women are afflicted in the same proportion. Sixty per cent of the cases occur in individuals over fifty years of age.

The outstanding symptoms are quite severe pain and hematuria; either of which occurred in all cases, and both of which occurred in over half of the cases. Other symptoms of urinary tract infection and irritation, and the sensation of a mass are much less common.

The direct diagnosis is suggested by the history of pain and hematuria and the presence of ureteral obstruction on ureteral catheterization with the *x*-ray films negative for stones in the urinary tract. A correct diagnosis was made or entertained in fourteen of the forty-nine cases. The differential diagnosis must exclude tumor of the kidney and renal stone.

The lesion is most often a papillary carcinoma. The non-papillary group include the squamous cell group, which probably arise from a metaplasia of the renal pelvis and ureter. The irritative action of stones has been involved by some as a factor in the metaplasia of the transitional epithelium of the kidney pelvis and ureter to a squamous cell type on the one hand, and as predisposing to carcinoma on the other hand. In only six cases were calculi present in the urinary tract. One of the outstanding sequelæ of prolonged ureteral obstruction is a hydronephrosis.

The prognosis is very grave; thirty patients dying while under treatment or within a few months. Among the remaining nineteen cases, one patient was well two and one-half years, and two other patients were symptom-free after one year.

The treatment of choice is uretero-nephrectomy.

Case report: A negro housewife of forty-eight years complained of constant pain in the left flank and left costo-vertebral angle, present for six weeks. She had also experienced night sweats, vomiting, distressing nocturia, and an increase in size of the abdomen. Examination revealed a feeble negress with a temperature of 101.2 and a pulse of 112. A large, hard, immovable tender mass was felt in the left upper quadrant. On

pelvic examination a large, smooth, round mass was palpated in the cul-de-sac, and which on cystoscopic examination was found to elevate the base of the bladder. *X*-ray examination of the abdomen was suggestive for stone shadows in the left kidney. The phenolsulphonephthalein output was five per cent in two hours. The blood urea was .81 mg. per litre of blood. The blood count revealed a moderate secondary anemia with a leukocytosis of 29,000. The urine contained a trace of albumin and pus cells. The patient died thirty-one days after the evacuation of the contents of a pelvic dermoid, running a progressively downhill course with a temperature of 99-101° F. At autopsy a benign dermoid surrounded by firm adhesions was found in the pelvis. A diffuse adenomyomatosis was present in the left tube. The left ureter was dilated to 0.5 cm. and contained small irregular elevated patches of tumor tissue in the upper 5.5 cm. of ureter. The midportion of the ureter presented a ureteritis cystica. The left kidney, enlarged to 17 x 13 x 10 cm., was composed of a multiloculated pyonephrotic sac containing two stones. The right ureter was dilated to 2.0 cm. and presented a ureteritis cystica and contained a large pointed stone completely occluding the ureter near the ureterovesical junction. The right kidney measured 16 x 10 x 9 cm. and its calyces and pelvis were extremely dilated. The tumor had invaded the left kidney and adjacent nerves; and metastases were present in the regional, perigastric and bronchial lymph nodes, adrenals, pancreas, liver, lungs and pleuræ. The tumor cells were of the squamous cell type with areas of prickle cells arranged in rounded islands or forming long finger-like processes dipping into the subjacent muscularis. The metastases resembled the parent tumor.

J. H. Rieniets, M.D.

TEMPORARY DIVERSION OF THE URINE BY PYELOSTOMY IN REPAIR OF THE URETER: Marc Iselin, Paris, France (Surg., Gynec. & Obstet., Oct., 1929, Vol. XLIX, No. 4, 503-509). The ultimate results of ureter reconstruction have been far from gratifying and it is almost a unanimous rule with French and German urologists that a kidney is lost after a ureter has been severed.

Ureters are usually injured during a pelvic operation. Poor results of the anastomosis; namely, stricture at the point of repair, hydro- or pyo-ureter, pyonephrosis, and perirenal infection, are, for the most part, due to the infectious nature of these operation, or because the surgical accident is not recognized at the time.

Obstruction occurs even in the absence of infection causing a hydro-ureter and pressure atrophy of the renal tissues. This process may be rapid or slow as shown by reports of cases up to twenty-seven years postoperatively, before the entire function was lost. However, Reed, Delbet, Brizaski, Friedrick, Bourniot, Rochet, Lenormant and Leibovici, Chifelian and Petit, have reported cases, followed over long periods of time, in which there was little or no renal impairment. With this evidence in hand it would be well to disregard the rule of most surgeons, who state that a nephrectomy should be performed in the case of a severed ureter, especially when one does not know the function of the remaining kidney.

The author considered stenosis as the cause of ureteral inertia and the resulting renal degeneration, and must therefore be prevented.

Traumatic lesions of the urethra resulted in stenosis (with few exceptions) before the use of cystostomy for diversion of the urine was used, since when, the results of urethral repair have greatly improved. Therefore the urine passing over the suture line must have something to do with the cicatrization and the author evolved the following technic:

Briefly: A pyelostomy performed and a bougie of sufficient size to fit the ureter snugly was introduced downward and held in place by a suture. A small catheter was placed in the pelvis (this was found to be useless later, as the fistula would remain open as long as the bougie was in place) and together with the short end of the bougie drawn out through the incision. A strip of gauze placed between the posterior edge of the kidney and the posterior abdominal wall (for 5 days) lessens infection.

Repair of ureter.—The end-to-end technic was used, being sure that all redundant mucosa was removed. The anastomosis was accomplished by four fine black silk sutures, using an eversion stitch and being sure that there was no mucosa between the muscle layers. With muscle to muscle and mucosa to mucosa quick regeneration occurs with a minimum amount of cicatrization.

Results.—The temporary pyelostomy remained open as long as the obstructing bougie was in place, but closed immediately upon its removal.

Peristalsis in the severed ureter was not hindered at the time of operation, but was absolutely inert after twenty-four hours and only a slight response in the distal portion. The proximal ureter continues to be inert although one animal showed some contractions by stimulation. The distal end showed intact peristalsis about one week alter.

If the anastomosis has been satisfactory and without stenosis, the contractions pass from one end of the ureter to the other without interruption at the end of seven weeks. Even with slight obstruction and ureteral dilatation strong contractions were observed.

In summary the author states that diversion of the urine permits cicatrization of the ureter without development of stenosis just as cystostomy checks the formation of traumatic stricture of the urethra. By preventing ureteral stenosis this procedure removes the cause of dilatation, atony, and finally complete renal atrophy.

L. G. Thomas, M.D.

CARCINOMA OF THE COLON—INTRAPERITONEAL VACCINATION BY MIXED VACCINE OF COLON BACILLI AND STREPTOCOCCI: Fred W. Rankin, and Arnold Bargen (Arch. of Surg., Vol. 19, No. 5, 906-914). Mortality statistics show the need of adopting useful methods to lower the death rate in this particular disease. The authors report the result of 60 cases between June 1 and November 6, 1928, in which intraperitoneal vaccine was used.

A majority of the patients reported received vaccine, the bacteria of which were isolated from patients who died of peritonitis. Vaccines were prepared separately of bacilli coli and streptococci and later a mixed suspension in sodium chloride was made with a density of about 1,000,000,000 organisms per cubic centimeter. Twenty-five hundredths of a c.c. of this vaccine made up to 1 c.c. with a physiological salt solution of sodium chloride was given subcutaneously one week before the anticipated date of operation. If no undue reaction occurred 1 c.c. of this vaccine in 10 c.c. of the solution was injected intraperitoneally the next day and a similar dose 2 days later. The patient was then given 2 days of rest and the operation was performed.

Reactions following intraperitoneal injections are similar, fairly severe, fever as high as 103.5 degrees F. within 2 to 4 hours after injections, diffuse abdominal soreness, some distension, occasional chills and leukocytosis. The reaction after the second intraperitoneal injection is lighter.

The mortality in the control group of 60 cases was 23 per cent; the mortality in the group which received intraperitoneal vaccine was 5 per cent.

The mortality lowering of 18 per cent, while it may not be enitrely attributed to the use of the vaccine, recommends it as a likely factor.

THE NUTRITION OF HEALTHY AND SICK INFANTS AND CHILDREN. For physicians and students. E. Nobel, C. Pirquet, and R. Wagner, of the Children's Hospital of the University of Vienna. Second edition rev. with 78 illus. and 6 charts. Authorized translation by Benjamin M. Gasul. Price $3.50. Philadelphia: F. A. Davis Co., 1929.

Pirquet's Nem system was devised during the war period for the purpose of feeding large groups of individuals on an economical basis. This book represents the first attempt to introduce this system to the English-speaking physician. It involves the replacement of our comparatively simple caloric system by a new, rather involved, and sometimes weird nomenclature. (Ex. sacratama, socrutomo, etc.) We have found Schick's concept of dubo (whole milk plus 17 per cent cane sugar) the only practical application of this method. It is pleasant to note that the authors urge the use of dubo as a concentrated food and not for complementary purposes. American pediatricians may take exception to the authors' three-hour nursing schedule for all infants. American mothers may object to a nursing schedule lasting an entire year. The clinical consideration of nutritional disturbances originated long ago with Finkelstein and was stressed by Von Reuss in his classic text on "Diseases of New Born."

With the omission of the generally unfamiliar nomenclature, the book assumes a very elementary aspect. We do not think that the average practitioner will profit greatly by a study of this book.

D. M. Siperstein, M.D.

BERIBERI IN LATE INFANCY: THE RESULT OF CELIAC DISEASE. Sidney V. Haas, M.D., New York (Arch. of Ped., August, 1929, Volume XLVI, No. 8). Beriberi is produced by a deficiency of vitamin B. It may be due, as in the cases to be reported, to an inability of the organism to abstract this substance from the ingested food.

Polished rice from which the pericarp and aleurone layers have been removed, when the chief article of diet, is the most common cause of beriberi.

Beriberi is a composite of three main sets of symptoms:

1. The symptoms of peripheral neuritis.
2. Cardiac insufficiency.
3. A generalized tendency to edema.

A study of celiac disease reveals in some of the severe cases the presence of all the classical symptoms of beriberi, edema, pallor, dyspnea, cardiac dilatation, parasthesias, weakness, irritability, and paralyses.

Beriberi is due to the absence of vitamin B from the diet. Celiac disease is characterized by an inability of the organism to utilize carbohydrates, the chief carriers of vitamin B. The end result in either case is the same whether vitamin B is not ingested or whether it is not absorbed.

The pathology of beriberi and celiac disease is the same, excepting that in beriberi nerve degeneration has been frequently demonstrated, while there is no report available of any case of celiac disease in which the nerves have been examined. The presence of paralyses in the latter disease makes it probable that examination of the nervous system would reveal such degeneration. The symptoms are almost identical excepting that constipation is common in beriberi; diarrhea, in celiac disease. Cardiac symptoms are often prominent in beriberi, while not prominent in celiac disease.

For a long time the resemblance of cases of celiac disease to the published description of beriberi made it seem probable that celiac disease and beriberi might be the same disease, but the absence of classical signs in other cases, made this conclusion unlikely.

R. N. Andrews, M.D.

DANGER SIGNALS IN NEW-BORN INFANTS: Julius Levy, M.D., Trenton, N. J. (Arch. of Ped., November, 1929, Vol. XLVI, No. 11). For the past 14 years in the City of Newark, there has been practically no reduction in the neo-natal mortality, that is, the deaths in the first month of life.

Cerebral hemorrhage is more common than is generally thought. In a study made of a large series of new-born, it was found that some bleeding occurred in as high as one-third of all births, often without any symptoms.

First is the importance of giving careful thought to an infant who fails to nurse successfully. When taken to the breast, it makes very little effort either to take the nipple or leave that nipple, that is, it is apathetic.

You should be suspicious about the new-born infant who is good, and who does not cry. The infant with cerebral hemorrhage does not cry easily, even under irritation.

Inanition. Another condition which is well to discuss is brought about by insufficient nutriment or water in the first few days, causing weight loss. If such an infant is being put to the breast regularly and apparently nursing, we are apt to believe that it is receiving sufficient nutriment and sufficient water. Weighing such infants before and after nursing has satisfied us that babies can go through sucking motions without abstracting practically anything from the breast. The supply of an ounce of water every three hours with possibly a five or ten per cent glucose solution will help to tide over these infants until the mother secretes more milk or the infant is put on artificial feeding.

The danger signals in a premature baby are, first, subnormal temperature; second, loss of weight, and sudden rise of temperature. An attempt should be made to keep the body temperature above 97 degrees and below 101. The subnormal temperatures are due to the immature and unstable heat centers. The danger of loss of weight is readily understood, since the premature infant is born without any water or fat reserve. Sudden rise in temperature is the result of infection, disturbances of metabolism, or an excessive supply of artificial heat. In order to maintain the body temperature, it is not necessary to have specially constructed incubators. Surrounding air should be between 85 degrees and 90.

Pyloric Stenosis. Well-nourished breast-fed infants who suddenly begin to vomit at or about 4 to 8 weeks of age should be suspected of having a pyloric spasm or pyloric stenosis. This vomiting is characteristic in that in the first place it starts rather suddenly and that the vomiting is much more profuse and much more energetic than the usual regurgitation or vomiting from indigestion. It is not uncommon to be informed that the vomiting was less after every change in formula. Atropin sulphate in proper dosage will control practically every case of pyloric spasm and pyloric stenosis. Doctors are unwilling or afraid to give the proper dosage. Infants six weeks old are given as much as one-twenty-fifth of a grain of atropin sulphate in 24 hours. Recently an infant 11 months old was cleared up in six weeks atfer receiving one-hundredth of a grain of atropin every three hours.

R. N. Andrews, M.D.

BREAST FEEDING: Jesse R. Gerstley, M.D., Chicago (Arch. of Ped., December, 1929, Vol. XLVI, No. 12). For centuries no one has disputed the superiority of maternal nursing, but still, for some reason or other, it has been subjected to relatively little scientific scrutiny.

Scanning the tables, one is impressed with several things. First, that in each baby the amounts taken at the individual nursings during the day were quite variable. In keeping with this, note the varying amounts of food taken daily in 24 hours. It will be seen that no days are identical. One of the most surprising observations is the enormous quantity of milk taken by the first baby at some of his nursings, even during the early months of life. As early as the fourth week it will be noticed that this baby took as much as 8½ ounces and two days later nine ounces at one 20 minute nursing.

Notice how much less the younger brother took when of the same age, and again note that the younger brother, even when he reached the weight of the older, still never took such quantities even though the breasts were full.

These results show what many pediatricians have felt and repeated frequently, that it is impossible to standardize the diets of infants. What they take depends primarily upon their own constitutional demands. We should take a lesson from this in bottle feeding. Maybe it would be wiser to expect the infant to show decided variations in the amounts taken in the individual bottles and in the daily 24 hours, rather than to expect him to show superhuman accuracy.

R. N. Andrews, M.D.

A FURTHER REPORT OF THE TREATMENT OF WHOOPING COUGH BY INTRAMUSCULAR INJECTIONS OF ETHER: Julius Levy, M.D., and A. S. Finkelstein, M.D., Newark, N. J. (Arch. of Ped., December, 1929, Vol. XLVI, No. 12). A report on the treatment of whooping cough by injections of ether was made in Archives of Pediatrics, July, 1928. It was pointed out on account of the high percentage of necroses, it did not seem to be a desirable treatment. Later experience with a modification in the method has caused them to change their opinion and they are, therefore, making a second report on the treatment of an additional 104 cases.

Of the 104 patients, 76, or 74 per cent, were termed *improved;* 23, or 22 per cent, were termed *unimproved;* 5, or 4 per cent, were termed *slightly improved.*

Ninety-four patients received the usual dosage of one ampoule intramuscularly, containing one c.c. of ether plus one c.c. of oil. Ten patients received double the dose, or two ampoules.

Among the entire 104 patients treated, no abscess or necrosis at the area of injection was seen. The meth-

od of treatment consisted of cleansing the skin with five per cent tincture of iodine, washing off with 95 per cent alcohol, giving the injection in the buttocks, alternating sites of injection. No other medication was allowed.

All the children bore the injections well. The age of the patient did not seem to enter into the matter of improvement or dosage. They suggest a further study with double the dosage, two c.c. of ether in two c.c. of oil, since it may be that a larger dose will bring even better results. The treatment at first is given every day.

R. N. Andrews, M.D.

SINUSITIS AND TUBERCULOSIS IN CHILDREN—Central Pulmonary Infection Secondary to Sinusitis in Children Simulating Juvenile Tuberculosis: Henry A. Reisman, M.D., Jamaica, N. Y. (Arch. of Ped., November, Vol. XLVI, No. 11). Although the two conditions may at first appear somewhat remote, the resultant pulmonary infections that may arise as a complication to a primary sinusitis may present a picture clinically, physically, and roentgenologically so similar as to be at times very confusing with that of juvenile tuberculosis. Sinusitis has long been recognized as a clinical entity, but it is only in the last several years that we have begun to appreciate its prevalence, complications and sequelæ. Dean, White, Oppenheimer, Marriott and others have reported sinusitis with considerable frequency in children.

The white race is anatomically peculiarly more susceptible to sinusitis than the colored race because of the tendency to and frequency of nasal obstruction in the former and wide nasal chambers with free drainage in the latter. Accordi, in 1911, stated that it should be regarded as an established fact when children suffer from frequent attacks of head colds that some of the accessory sinuses are involved.

All cases of sinus infections should be regarded as potential chest cases just as all cases of tonsillitis are regarded as potential cases of cervical adenitis.

Mullin and Ryder in 1921 found, first, that the lymphatic drainage of the antrum is by way of the submaxillary and retropharyngeal glands into the internal jugular nodes and deep cervicals, then into lymph ducts, great veins, right side of heart and into the lungs by way of the pulmonary artery; second, extension by inhalation.

The association of sinus and pulmonary infections has been noted too often to be coincidental. The incidence of sinus involvement and the result of the treatment of the sinusitis upon the pulmonary infection were striking. The general condition greatly improved.

Possibly a large proportion of non-specific chronic pulmonary infections, which have been observed in the past, have been the result of unrecognized and untreated sinusitis.

The physical signs in the chest are almost identical in the early stages of both conditions. When râles are present, the râles secondary to sinus infection are usually of the large moist character, whereas those from the tuberculous infection are of the fine crepitant type. It is surprising how many of these children have no symptoms or clinical evidence pointing to sinus disease despite the existence of the same.

If the tuberculin test is negative we must then look elsewhere for the cause of the pathology in the central lung field and it will often be found in the sinuses. But if the tuberculin test be positive and sinusitis present, it is a difficult problem to tell how much of the superimposed pathology could be attributed to secondary changes from the sinusitis and how much to the tuberculous focus.

R. N. Andrews, M.D.

A FURTHER CONTRIBUTION ON CELIAC DISEASE: Charles Gilmore Kerley, M.D., New York (Arch. of Ped., January, 1930, Vol. XLVII, No. 1). The author looks upon celiac disease as a clinical entity and not simply an aggravated chronic gastro-intestinal indigestion. Every case presents the classical signs of extreme emaciation, large abdomen, copious, foul stools, anorexia or capricious appetite, the characteristic facial expression, and greatly disturbed mental reaction.

The plan of management is to discontinue milk in all forms and combinations and use a powdered casein. The Walker Gordon Laboratory prepares the casein mixture in most of the cases after the following formula:

Casein (sodium caseinate)	2¼ ounces
Starch (baked barley flour)	2¼ ounces
Sugar (can, lactose or karo)	2¼ ounces
Water	30 ounces

This combination gives a caloric value of about 16 per ounce.

Early in the case, the author uses the casein, starch, sugar mixture as the only means of nourishment together with a teaspoonful of sherry wine diluted with a small portion of water at two or three-hour intervals. After a few days, perhaps a week, ground rare beef, white meat of chicken, powdered hard-boiled egg yolk, gelatine pudding, banana and bread crusts are added. He endeavors to give orange juice early in every case. As a rule, cod liver oil is not well tolerated even in small amounts and it is rarely used.

When the acute symptoms are somewhat in hand, a decoction made from potato, turnip, carrot and celery is given in small amounts. Relapses of a temporary nature often occur and the stools return to the former characteristic odor and appearance.

Cases in which there is a tendency to diarrhea he gives 20 grains of bismuth subnitrate every two hours with small dosage of Dover's powder.

The satisfactory results in these cases are due to the fact that cow's milk was entirely omitted from the diet.

R. N. Andrews, M.D.

MUCOUS AND UMBILICAL COLIC IN CHILDREN: George J. Feldstein, M.D., Pittsburgh, Pa. (Arch. of Ped., January, 1930, Vol. XLVII, No. 1). The diagnosis of the cause of abdominal pain in children demands even more frequently than in the adult a consideration of conditions extraneous to the abdomen itself. The most familiar example is the referred pain to the abdomen, as in cases of pneumonia, pleurisy, endocarditis, pericarditis, the intestinal form of influenza, and the abdominal pains of throat infection.

There are, in addition to these causes, two conditions of great clinical importance in childhood—mucous and umbilical colic, which may simulate more serious abdominal conditions.

These forms of abdominal complaint in children have as a background two factors, as a rule: (1) An hereditary constitutional tendency; (2) Bad environmental surroundings.

It was Moro who pointed out that cases of umbilical or navel colic have nothing to do with appendictis, and are to be handled by suggestive treatment. These cases are characterized by frequently recurring attacks of apparently violent abdominal pain, which are mainly referred to the region of the umbilicus. Frequently there is vomiting.

The cause of this peculiar type of colic is cramplike contractions of the bowel.

Mucous colic which is similar to umbilical colic in its etiology, severity of the abdominal complaint, and which occurs in the same type of neuropathic children, is characterized by the periodic passage of large masses of mucous often in the form of tubular casts, ribbons, or shreds, with violent colic and tenesmus.

In umbilical colic there is no inflammation in the intestinal tract. It is purely a secretory neurosis in constitutionally predisposed children, and is due to hypersecretion of the glands of the intestinal mucosa.

Treatment of Mucous Colic: Colonic irrigations with salt solution or enemata of oil are of value in acute cases or in the sub-acute. In cases with a tendency to diarrhea, the diet should be mainly protein. Sodium bromide should be used to quiet the underlying neuropathic condition. Suggestive treatment as for navel colic is also indicated. The treatment of cases having a neuropathic basis only is chiefly by suggestion.

R. N. Andrews, M.D.

CHOREA: ITS GENESIS AND ITS CLASSIFICATIONS: J. Epstein, M.D., New York (Arch. of Ped., Feb., 1930, Vol. XLVII, No. 2). Chorea is a constitutional neurosis. In many cases there is a familial tendency. The choreic disorder is most common during childhood, when the nervous and psychic mechanisms have not yet acquired the poise, steadiness and orderly conduct essential to proper neuro-psychic functions. Chorea may be divided into three classes: Pathologic, or infectious chorea, physiologic or functional chorea, and psychologic or emotional chorea.

Pathologic or Infectious Chorea.—Chorea was definitely traced to rheumatic infection as the exciting cause. In all cases of pathologic or infectious chorea, the infection acts only as an exciting cause on an underlying choreic neurosis.

Physiologic or Functional Chorea.—These children were unusually active, irritable, quick and irregular in their actions. When to this physiologic hyperfunction was added some unusual physical or mental pressure, reflex irritation, thyroid overwork, puberty, the onset of menstruation, or any other new physiologic demand, a choreic disorder was the result.

Psychic or Emotional Chorea.—These children were extremely emotional, subject to convulsive attacks and night terrors. Others laughed unduly and displayed a violent temper. An added sudden mental shock as from fright or grief precipitated an attack of chorea.

Diagnostic Symptoms and Signs.—The symptoms and signs of chorea are the result of both the primary neurosis and the secondary etiologic factors. In all cases there is twitching, turning, twisting or jerking of the various parts of the body, due to irregular, discordant contractions of groups of muscles. The entire motor system may be said to be in a state of fibrillation.

Chorea in itself offers a favorable prognosis. It is the damage to the heart that makes chorea a formidable disease. Post-choreic endocarditis is quite common in the infectious type of chorea. Chorea frequently injures the nervous and psychic systems of the child. A close observation will show that these children react abnormally to the ordinary physiologic and psychologic events of life.

Treatment.—Physical and mental rest are imperative. Foci of infection must be removed. Hydrotherapy in the form of warm baths or cold spronges, depending on the child's reaction, are very useful .

R. N. Andrews, M.D.

BISMUTH THERAPY EXCLUSIVELY IN CONGENITAL SYPHILIS: John F. Coppolino, M.D., Philadelphia (Amer. Jour. of Dis. of Children, February, 1930, Volume 39, Number 2). Congenital syphilis has always been refractory to treatment. Since the introduction of bismuth as an antisyphilitic agent, much has been written of its use in acquired syphilis, but comparatively little concerning its value in the congenital form.

The preparation used was bismuth salicylate in oil suspended together with camphor and creosote, 1 c.c. of which contains 130 mg. of metallic bismuth. In the earlier cases he started with a dose of from 15 to 30 mg. in young infants, and 65 mg. in older children. The dose was increased to 65 mg. for children under 1 year of age, and to 130 mg. in older children.

The course of treatment consisted of twenty injections at weekly intervals. A blood test was taken at the beginning and termination of each course, and if it was positive, the treatment was immediately continued; if negative, a four weeks' rest was allowed. The maximum number of courses administered was three, after which the patients returned every month for examination and blood tests.

The injection is given alternately and deeply into

the upper and inner quadrant of each buttock. Care must be exercised that a blood vessel is not encountered as evidenced by drawing blood into the syringe. After the injection has been made, the syringe is disconnected from the needle, which is left in situ. Air is drawn into the syringe and injected. This clears the canal made by the needle of any bismuth that may be forced back, especially if the muscles contract. The needle is then withdrawn, firm pressure applied and the part massaged. If this is done, then infiltration and induration previously reported will be reduced to a minimum.

Conclusions.—(1) Bismuth in rather large doses is apparently well tolerated by infants and children. (2) It is useful in the treatment of older children, but does not effect cure. (3) It is more efficacious in young infants, rendering them both symptom-free and serologically negative. (4) No absolute valuation of the drug can be made at the present time. These cases should be followed for several years to determine the permanency of results.

MAYO CLINIC, ROCHESTER

ROENTGEN DIAGNOSIS OF LESIONS OF THE JEJUNUM AND ILEUM. Max Ritvo, M.D. (Am. Jour. Roent. Feb., 1930, XXIII, 160). A brief résumé is given of the conditions affecting the jejunum and ileum which can be demonstrated by X-ray examination. These lesions are relatively rare but of great importance when present. Diagnosis by clinical methods is very difficult and often impossible and the roentgen examination is frequently the only method of arriving at a diagnosis preoperatively.

The conditions discussed are:

1. Obstruction—this can be studied by plain films of the abdomen or after the administration of an opaque meal.
2. Hypermotility—this is best studied both fluoroscopically and by films made at intervals.
3. Diverticula—these may be single or multiple.
4. Malpositions and displacements—these are relatively common.
5. Adhesions—these are best observed by roentgenoscopic studies.
6. Tuberculosis—is located most commonly in the cecum and terminal ileum and shows irritability with hypermotility and filling defects.
7. Ulcers—these are difficult to diagnose.
8. Neoplasms—these are very rare and difficult to demonstrate.
9. Foreign bodies—the opaque ones are easily demonstrable.
10. Postoperative changes—this is particularly valuable in demonstrating function following gastroenterostomy.

The roentgen findings of each of these conditions are discussed briefly and the chief diagnostic points outlined.

Jacob Sagel, M.D.

THE PRESENT STATUS OF HYSTEROSALPINGOGRAPHY: A. R. Witmer, M.D., H. P. Cushman, M.D., and T. Leucutia, M.D. (Am. Jour. Roent., XXIII, Feb., 1930, 125). The authors present a very complete review of the literature and a report of 512 personal cases. The various contrast media used in hysterosalpingography are described and the advantages and disadvantages of each presented. Their technic is also given.

They conclude that hysterosalpingography by means of lipiodol is a safe and simple procedure. The method is of great diagnostic value in developmental anomalies of the genital organs, in tubal affections leading to sterility, in certain very carefully selected cases of pregnancy in which therapeutic abortion is indicated or where a differential diagnosis from other obscure conditions is essential, in uterine tumors, excepting malignancies, and in certain extra-uterine tumors. The contraindications are recent hemorrhage, inflammatory conditions that are not completely quiescent, active infections or malignancies involving the cervix, previous intra-uterine interventions, ectopic gestation or uterine gestation in which a therapeutic abortion is not desired, infected uterine or cervical polyps and fever. In certain instances the injection of lipiodol is of direct therapeutic valuee.

The article is accompanied by 49 plates illustrating the conditions described.

Jacob Sagel, M.D.

INTERPRETATION OF ROENTGENOGRAMS OF CHEST IN CHILDREN BASED ON OBSERVATIONS OF NECROPSY: John A Bigler, M.D., Chicago, Ill. (Amer. Jour. Dis. of Child., Nov., 1929, Vol. 38, No. 5, p. 978). One hundred seventy-one pairs of lungs were examined post mortem. These children died in hospitals which do not admit contagious or open tuberculosis cases.

During life roentgenograms were made at intervals. After death a roentgenogram was taken of the chest and finally of the excised lungs inflated with air. Sometimes opaque substances were injected into the circulatory system of the lungs, the bronchial tree, or both, and pictures taken. Some of the lungs were fluoroscoped from different angles. The lungs were then dissected and microscopic sections made.

Even under the ideal conditions afforded by roent-

genograms of excised lungs the bronchi could rarely be followed farther than the inner third of the lung field. In the injected lungs the bronchi could be followed to the periphery. Circular areas of decreased density near the hilum are caused by bronchial branchings, parallel to the axial ray. They become opaque in the injected lung.

The linear markings were more marked and showed finer detail in the pictures of the excised lungs with the vessels from the heart tied off so that no blood could escape. When the blood was washed out of the pulmonary vessels, the markings became less distinct. The beaded shadows of the trunks disappeared. Injection of these vessels increased the linear markings.

Linear markings are due to blood in arteries and veins and to a lesser extent to the bronchi. Blood vessels give shadows of even density; bronchi give two shadows with a narrow band of decreased density between. Nodular areas along the linear markings are not due to tubercles or lymph nodes, but branches of blood vessels parallel to the axial ray.

Round, definitely circumscribed areas of increased density in the hilum or inner third of the lung fields are not due to lymph nodes or scars, but to branches of large blood vessels. They practically always occur in the course of the linear markings and change position or disappear on successive exposures.

Dissection showed lymph nodes present in every hilum. Increase in size and number of these nodes did not cast shadows on the films. Only nodes that contained calcium were recognized in the roentgenograms of excised lungs.

In children that died after measles or pertussis, the hyperplastic, inflammatory tracheobronchial glands cast no characteristic shadows. The increase of hilar shadows in these cases is explained by pressure atelectasis, and inflammation with exudation of the surrounding lung tissue.

Caseous lymph nodes also failed to cast shadows unless they contained calcium.

It is therefore concluded that normal lymph nodes cast no shadows; hyperplastic nodes, whether caseous or inflammatory, whether in the hilum or intrapulmonary tissue, cannot be recognized if they do not contain calcium. They will not cast shadows unless they are large enough to encroach on the pulmonary fields.

G. J. Ferreira, M.D.

BRONCHIAL OBSTRUCTION—ITS RELATION TO ATELECTASIS, BRONCHOPNEUMONIA AND LOBAR PNEUMONIA: Pol N. Coryllos, M.D., and George S. Birnbaum, M.D. (Amer. Jour. Roent., Nov., 1929, XXII, 401). The authors present a roentgenographic, experimental, and clinical study of bronchial obstruction and its relation to atelectasis and pneumonia. Bronchial obstruction is a factor common to both of these conditions, the only difference being the nature and virulence of the microörganisms present in the occluding exudate. The lobar pneumonias and atelectases were produced by bronchoscopic methods and checked by serial roentgenograms which showed a striking similarity in appearance. Seven possible objections to this theory are discussed.

The authors conclude that lobar pneumonia is a pneumococcic atelectasis due to bronchial obstruction by mucous exudate infected with virulent pneumococci, and that atelectasis or apneumotosis (generally, but not always, a postoperative pulmonary complication) is due to bronchial obstruction with mucous exudate infected with pneumococcus Group IV, an organism of low virulence. The role of bronchitis in the evolution of the disease syndrome is represented by: bronchitis—atelectasis—pneumonia.

The article presents an excellent study of this subject and is well illustrated by roentgen plates of both human beings and animals, and gross and microscopic pathology. A review of almost the entire literature is included.

EYE, EAR, NOSE AND THROAT

SUPERVISORS:
VIRGIL J. SCHWARTZ,
MEDICAL ARTS BLDG., MINNEAPOLIS

ARTHUR C. DEAN
HOT SPRINGS, SOUTH DAKOTA

THE TONSILS AND SOME EXPERIENCES OF THEIR SURGICAL TREATMENT: Herbert Tilley, F.R.C.S. (Eng.), London (Surg., Gynec. and Obstet., Jan., 1930, 1.1A. 167). Résumé of an address presented before the Clinical Congress of the American College of Surgeons, at Chicago, Oct. 14-18, 1929.

After a somewhat apologetic introduction for the subject of discourse the author steps into the various phases and conditions one is liable to encounter and also some of the abnormalities seen in the practice of an otolaryngologist.

The term "supra tonsillar fossa" comes in for his first criticism. He states that since that space is lined with epithelium, contains more or less loose lymphoid tissue and is within the capsule of the tonsil it would be more correct to speak of it as the "tonsillar fossa."

In passing he mentions a long ossified stylohyoid ligament as well as isolated spicules of bone and cartilage. These he thinks are embryonic "rests" of the branchial arches. The author next presented a specimen of an osteoma removed from the tonsillar fossa and the soft palate. Tonsillar calculi cause pain in the tonsil when swallowing and also in the depth of the aural meatus. This cause of deep aural pain is often overlooked. He next calls attention to the protective function of Waldeyer's ring and the presence of a lateral pharyngeal ring in many cases where tonsils have been removed early in life. The presence of tonsillar tissue in the lower part of the fossa is often the result of the lingual tonsil pushing upward instead of

having been left by a previous operator. This he attributes to compensatory developments.

Tonsillar surgery is indicated in some cases of diphtheria when a throat will not give a negative culture; in some cases of so-called tuberculous infection of the lymph glands; in chronic arthritis; and malignant disease. He does not take a stand as to the time to operate in cases of so called rheumatism.

Among the complications of tonsillectomy he first mentions hemorrhage; next, pulmonary complications. To prevent hemorrhage he ligates the descending branch of the posterior palatine artery in every case and if necessary the tonsillar branch of the facial. He removes the tonsil by dissection in all cases. Of pulmonary complications he has had no experience, so says little about them.

ARTHUR C. DEAN, M.D., F.A.C.S.

SOME POINTS IN THE TREATMENT OF MENINGITIS: G. J. Jenkins (Jour. of Laryng. & Oto., Vol. XLIV, No. 4, p. 239). In many cases of meningitis secondary to septic middle ear disease, the infection has not reached the sub-arachnoid space, so these cases can be treated well by the complete removal of the external inflammation. But this should be done only early in the disease and in any case where we suspect the infection has extended to the sub-arachnoid space, it should be opened and washed out.

Lumbar puncture is dangerous and should be done only as a diagnostic procedure, and then only 6 cc. should be withdrawn. In borderline cases it is well to wash out the sub-arachnoid space, as the risk is no greater, if one carefully cleanses the wound before doing so.

The principle of the following procedure in a case, for instance, of meningitis secondary to septic labyrinthitis, is to drain the meninges from the point of maximum infection, i.e., the labyrinth, and encourage the flow of cerebro-spinal fluid through this area, by washing through from the lumbar region.

In preparation no morphine or atrophine should be used. Prepare some iodoform by washing it free of perchloride with modified Locke's solution. Then 6 cc. of spinal fluid is removed by lumbar puncture and sent to laboratory.

A superior and inferior labyrinthotomy operation is done. The wound is washed with hydrogen peroxide and saline, then with 2 per cent alcoholic solution of iodine. A fine needle is passed into the labyrinth and the latter is then washed with the iodine solution. It is now determined by the pathologist's report if further procedure is necessary. If so, fresh instruments and supplies are used. Lumbar puncture is repeated allowing only 1 or 2 drops of fluid to escape, so determining if the needle is in the sub-arachnoid space. The lumbar puncture needle is left in. Then an opening is made into the internal auditory meatus, through the inner wall of labyrinth. When the flow of fluid is established the lumbar puncture needle is connected with a reservoir of modified Locke's solution. A piece of silk-worm gut is inserted into the wound and this is left as a drain. When a few ounces of solution have passed through, serum containing 8 grains of the prepared iodoform is injected through the lumbar needle. Locke's solution is again allowed to flow until the return from the ear is clean.

Sometimes when the internal auditory meatus does not afford drainage, the cisterna pontis may be reached in front of the cerebellum. In this route considerable bone must be removed behind the lateral sinus, so a drain may be inserted along the posterior surface of the temporal bone through the dura and internal to the sinus. The wound should be packed with iodoform gauze.

As the blood pressure is always low attempts should be made to increase it, and thus increase the flow of cerebro-spinal fluid.

If drainage ceases too early it may be necessary to reëstablish it and in some cases to rewash the sub-arachnoid space.

L. G. FLANAGAN.

ACUTE PURULENT MENINGITIS OF AURAL ORIGIN: J. P. Stewart (Jour. of Laryng. & Oto., Vol. XLIV, No. 4, p. 225). The series of cases on which this report is based consists of seventy-eight cases following chronic, and thirty-six acute, purulent middle ear conditions. These cases occurred at the Edinburgh clinic. Acute purulent meningitis occurs chiefly before middle life, seventy-four per cent occurring before the age of thirty. It also seems to be predominant in males.

The early clinical manifestations are chiefly due to irritation in the posterior fossa, this because of the aural origin of the infection. There is anxiety and confusion, with deep severe headaches in the frontal region but shifting frequently. Frequent first complaints of the patient are pain on brushing the hair and stiffness of the neck. The temperature rises rapidly and remains elevated but the pulse and respiration are at first slow, due to vagal irritation, but towards death rapidly rise. Mendel found early hyperaesthesia of the posterior meatal wall, due, presumably, to the reflex transmission of pain from the inflamed meninges, since the auricular branch of the vagus is connected with the meningeal nerves through the jugular ganglion. Frequently there is pain on pressure over the atlanto-occipital membrane when the tension of the cerebro-spinal fluid is elevated. Usually there is a leucocytosis of about 20,000 with a polymorphonuclear predominance.

The cerebrospinal fluid early is clear or slightly turbid, with the pressure varying, although increased. The cell count is above 4 per cubic mm. There is only a trace of globulin and the total protein is increased. Later the fluid is turbid to purulent and the cell count is increased, with also a relative increase of polymorphonuclears. The chlorides and glucose decrease.

In making the diagnosis serous meningitis is ruled out by the high cell count. Cerebellar abscess usually has a cell count of below fifty, with a small lymphocytic predominance; its chloride content is usually unaltered and the glucose is increased. The fluid is always

sterile. Meningism occurs only in young children, and the fontanelle pulsates.

The prognosis is generally bad. In this series there was a 93 per cent mortality, only one of the acute ear cases recovering. Early diagnosis, however, and operative procedure improve the percentage.

The only chemical treatment of any value consists of 50 cc. of 10 per cent sodium chloride daily. The operative treatment regardless of origin depends chiefly on free drainage of the cerebro-spinal fluid. Continuous drainage should be established, if possible, as through the internal auditory meatus, or by frequent spinal drainage. Seven of the eight cases recovering had daily spinal punctures, and the other had good drainage through the labyrinth. Added to this there must be drainage of the original source of infection and free exposure of the dura, since all recovering cases had a radical mastoid performed.

L. G. Flanagan.

THE HOROVITZ PROTEINS AND LIPOIDS AGAIN

"Lipoidal substances" and "protein substances" are marketed under various names by variously named firms. Always, apparently, the chemistry is performed by and the claims are made through A. S. Horovitz. In 1915 it was an alleged cancer cure, "Autolysin," a poultice or extract made from a number of herbs. Then came the "Proteogens" of the William S. Merrell Co., reported on unfavorably by the Council on Pharmacy and Chemistry in 1918. They were numbered, different ones being for the treatment of different diseases. These mixtures of vegetable proteins were exploited to physicians by a sad outpouring of pseudoscience. Next Horovitz became identified with the Horovitz Biochemical Laboratories, with a line of "Protein Substances" similar to the "Proteogens," each claiming to be more or less specific for some disease. Now the successor to the Horovitz Biochemical Laboratories is the Lipoidal Laboratories, Inc., and a number of supply houses act as agents for the firm. "Gonolin," "Luesol," "Osmogen," "Arthritine," "Asthmazine" and other preparations similar in stated composition and therapeutic claims to the Proteogens are now promoted for physicians who think that the "bosh" in the circulars is good science because it is so confusing that it is not comprehensible. (Jour. A. M. A., December 21, 1929, p. 1975.)

THE ETIOLOGY OF INFLUENZA

I. S. Falk and his colleagues publish a preliminary report of their work on the etiology of influenza which does not go far beyond previous research on influenza. The difficulty in interpreting the results is largely due to the fact that it is difficult to distinguish clinical epidemic influenza from acute respiratory infections in monkeys and, indeed, in man. In 1892 Pfeiffer described an organism as the causative organism of influenza and since that time other allegedly causative organisms have been described. The green-producing streptococcus isolated by Mathers and Tunnicliffe in 1918, the one isolated by Rosenow in 1919, the filter-passing organism described by Meyer in 1919, and the organism discovered by Olitzky and Gates called *Bacterium pneumosintes,* would seem to deserve as much consideration as should be given, at least on the basis of the available evidence, to the germ recently announced by Falk. (Jour. A. M. A., December 28, 1929, p. 2034.)

MALLOPHENE

Mallophene is the proprietary name under which the Mallinckrodt Chemical Works markets an azo dye of the pyridine series. The patents on the product are owned by another corporation and the Mallinckrodt firm manufactures it under license from the holding company. It is regrettable that the Mallinckrodt Chemical Works sees fit to use for this preparation a different proprietary name from that used by the patent owners. The use of a number of proprietary names for identical products creates chaotic conditions. Mallophene has not been submitted to the Council on Pharmacy and Chemistry, although the firm which owns the patent has submitted its product to the Council. The Mallinckrodt firm does not appear to have presented evidence to justify the medical claims which it advances. It is to be regretted that the Mallinckrodt Chemical Works offers its product to the medical profession without first submitting it to the Council on Pharmacy and Chemistry—a recognized body working in the best interests of both the profession and the public health. (Jour. A. M. A., December 28, 1929, p. 2044.)

UVIOL-JENA ULTRAVIOLET TRANSMITTING GLASS ACCEPTABLE

The Council on Physical Therapy reports that the window glass known as Uviol-Jena, manufactured by Schott and Gen., Jena, Germany, and submitted to the Council by the Fish-Schurman Corporation, New York, is stated to be "a glass which transmits the biological ultraviolet rays of the sun" and "in a thickness of 2 millimeters transmits at the time of installation about 60 per cent of the ultraviolet rays of a wave length of 302 millimicrons" and "even after 'solarization' it still transmits about 48 to 45 per cent of these same rays." The Council reports that acceptable evidence in favor of these claims was submitted, and hence declares it acceptable for inclusion in its list of accepted devices for physical therapy. (Jour. A. M. A., December 14, 1929, p. 1887.)

MEDICAL TREATMENT OF CATARACT

About every five years, the ophthalmic world is thrilled by the announcement of a new medical cure for senile cataract. This has been going on for at least two hundred years. Boric acid and glycerin, ethylmorphine hydrochloride, subconjunctival injections of mercuric cyanide, radium, antigenic injections of lens proteins, mixed endocrine glands, sodium iodide in all possible combinations, and so on, have all had a trial. Not one of them has been scientifically established as of value, and more cataracts are being operated on than ever before. (Jour. A. M. A., December 14, 1929, p. 1910.)

EXAMINATION REPORT, MINNESOTA STATE BOARD OF MEDICAL EXAMINERS, JANUARY, 1930

BY EXAMINATION

Name	School and Date of Graduation	Address
Anderson, Philip Andrew	U. of Minn., M.B., 1928; M.D., 1929	11 Nourse St., St. Paul, Minn.
Arlander, Clarence E	U. of Minn., M.B., 1929	General Hospital, Minneapolis
Barnet, Emmanuel Green	U. of Minn., M.B., 1929	St. Joseph's Hospital, St. Paul, Minn.
Benson, Theodore Quentin	U. of Minn., M.B., 1929	515 Delaware St. S.E., Minneapolis
Berghs, Lyle V	U. of Minn., M.B., 1928; M.D., 1929	Owatonna, Minnesota
Bjelland, Paul A	U. of Minn., M.B., 1929	200 Oak Grove St., Apt. 206, Minneapolis
Church, Gerald T	Syracuse Univ., M.D., 1927	Mayo Clinic, Rochester, Minn.
Cummings, William G	U. of Minn., M.B., 1928; M.D., 1929	Glen Gables, Park Ave., Glencoe, Ill.
Decker, Fred Henry	Rush, M.D., 1927	Mayo Clinic, Rochester, Minnesota
Gregory, Raymond Leslie	U. of Minn., M.B., 1929; M.D., 1929	General Hospital, Minneapolis
Harris, Milo Truman	U. of Texas, M.D., 1928	Ancker Hospital, St. Paul, Minn.
Holte, Herman James	U. of Minn., M.B., 1929	3707 Columbus Ave., Minneapolis, Minn.
Hyde, Theodore Lincoln	Harvard, M.D., 1927	1301 1st St. S.W., Rochester, Minnesota

WANTED—Salaried appointments for Class A Physicians in all branches of the medical profession. Let us put you in touch with the best man for your opening. Our nation-wide connections enable us to give superior service. Aznoe's National Physicians' Exchange, 30 North Michigan Ave., Chicago. Established 1896. Member The Chicago Association of Commerce.

OPEN FIELD for enterprising young doctor in thriving Canadian border town 1,000 population across river from Canadian town about same size. Only one other doctor in whole county. Excellent opportunity. Address D-60, care Minnesota Medicine.

LOCUM TENENS open for four months beginning April or May in town of 850 population, southwestern North Dakota. No opposition. Big territory. Possibility of taking over practice or partnership later on. Address D-62, care Minnesota Medicine.

FOR SALE—7 hospital beds; 6 bedside tables; 1 operating table; 1 irrigating stand and basin rings; 1 two-ring basin stand; 2 side tables; 1 stool; 1 microscope, Bosch & Lomb (excellent condition); basins, pitchers, etc.; 1 National sterilizer, hospital size. Write D-61, care Minnesota Medicine.

PHYSICIAN'S OFFICE FOR RENT.—Best location Midway district, corner Thomas and Hamline. Rent $25 a month. Inquire at dentist's office.

PHYSICIAN WANTED—Young physician wanted to share office with internist, Medical Arts Building, Minneapolis. Office available until 3 P. M. every day. Address D-59, care Minnesota Medicine.

EXPERIENCED PHYSICIAN desires substitute work for a few months. Address D-63, care Minnesota Medicine.

MANIFESTATIONS OF HYPOTHYDROIDISM IN THE LIMITED FIELDS OF MEDICAL PRACTICE*

C. A. McKinlay, M.D.
Minneapolis

WITH the increasing use of simplified methods to estimate the heat production of the body, the clinician has available a supplementary method of studying disease which is valuable in proportion to the appreciation of all factors that alter such determinations. The chief application of clinical calorimetry to endocrine, particularly thyroid disease, sometimes leads to errors in diagnosis and therapeutic application which would be obviated if broader and more fundamental conception of nutrition were kept in mind. If an analogy from animal biology may be permitted, the marmot decreases its heat production 25 fold upon hibernating. In this instance the extreme lowering of the basal metabolism is related to physical and chemical factors and not primarily to changed thyroid function.

Starvation profoundly affects the basal metabolism. Benedict and associates[1] found in a group of twelve young men on a net available diet of 1,375 calories suddenly reduced from 4,000 calories in three weeks, that the average basal metabolism had dropped 27 per cent per square meter of body surface and that the individuals lacked physical strength and sense of well being. Lusk[2] states that there is specific reduction of the basal metabolism coincident with undernutrition, an innate protective mechanism. In contrast to this, high calorie and high protein diets tend to increase the basal metabolism. A very low basal metabolism personally observed, approximately minus 40 per cent, was noted in a dispensary patient markedly underweight who was starved on account of a gastro-intestinal condition and who was without thyroid disease. Likewise, an illustration may be taken of the neurotic individual with mucous colitis who cannot or will not eat sufficient food to maintain normal body weight and who has reduced heat production independent of any thyroid relationship. Inanition in the diabetic, formerly more prevalent, also tends to lower the oxidative processes. Indeed, any study of the basal metabolism of an individual may lose its significance as a therapeutic guide if factors such as inanition are neglected, which often are unrelated to thyroid function. In this connection it is worthy to note the complex of hysterical dysphagia first pointed out by H. S. Plummer and described by Vinson.[3] Plummer suggested that during the long period of inanition a light demand for thyroxin results in a disuse atrophy of the thyroid and that hypothyroidism may develop after the patient begins to swallow freely due to inability of the thyroid to furnish secretion enough to care for the increased food intake. Although noted in a rare condition the mechanism described may account for the lowered metabolism in more common forms of inanition. It may also be noted that physical inactivity over appreciable periods of time tends to lower the oxidative processes of the body.

An attempt has been made in this study to evaluate all the possible factors that influence the nutritional state of the individual and not alone the status of the thyroid without unreasoned emphasis upon the laboratory procedure of determining the basal metabolism. In this study, cases with lowered basal metabolism not due to other demonstrable cause who showed favorable therapeutic response to thyroid extract have been designated hypothyroidism. Clinical observations are noted upon thirty cases selected from a series representing all types of thyroid disease seen in dispensary and private prac-

*Read before the Minneapolis Clinical Club, Feb. 20, 1930.

tice. Myxedema is not included. The features of total loss of thyroid function are characteristic and well known even though an occasional patient is found who has drifted for years without detection of the disease. But partial loss of thyroid function presented here under the term hypothyroidism has presented such variations that they seem to be worthy of brief comment. Diversity of clinical pictures would be expected on a physiologic basis when the thyroid is considered as a regulator of oxidative processes which influence all the tissues of the body. Manifestations of thyroid deficiency have been noted with the predominating symptoms falling within the realm of several different fields and should be of interest to a diversified group such as this.

The skin has often given little or no manifestations in this group with partial loss of thyroid function. Dryness and scaliness have sometimes prevailed without the cutaneous and subcutaneous edema or pseudo-edema which characterizes and gives myxedema its name. Experimentally, hair loss may be shown to be due to diminished thyroid function. Indeed, in experimental animals after reduction or loss of thyroid function, hair changes, thinning and dryness are the most striking features. The veterinarians speak of the hairless pig malady in the northwest due to iodin and thyroid deficiency.

Especially interesting has been the relation of alopecia to thyroid function. Thinning of hair and eyebrows is not uncommon in myxedema. Nearly complete alopecia developing in a woman, M. R., aged 48, was associated with retarded thyroid function; the use of thyroid extract continued over a period of some months restored in a large measure the growth of hair. In other individuals in this series, chiefly females, hair changes were noted although not as the presenting symptom. On the other hand, acquired alopecia totalis in one young man had no demonstrable relationship to thyroid function, which was entirely normal. Partial alopecia in men has no demonstrable relation to thyroid function.

One case of scleroderma, C. M., a female, aged 38, showed retarded metabolism and presumably retarded thyroid function without, however, appreciable response to thyroid therapy. In another case, H. S., a female, aged 31, with reduced metabolism, cloasmic pigmentation of the face was markedly improved by the use of thyroid extract. Of interest also in this connection was the reported appearance of urticarial lesions in two individuals following the use of thyroid extract. Occasional swelling of ankles has been noted.

Undoubtedly, very important interrelationships known even to the ancients according to Marine[4] exist between thyroid and ovarian function. Dr. Litzenberg[5] and others have recently emphasized interference with reproductive function associated with diminished basal metabolism and its treatment by thyroid extract. One individual in this series, H. A. K., a female, aged 30, had definite hypothyroidism with a history of a previous stillbirth and sterility thereafter. Several years later, after normal thyroid function was restored, pregnancy supervened and terminated in another stillbirth; no other cause of which was found by the obstetrician. In the group studied, amenorrhea has usually been associated with other symptoms such as obesity, anemia, and colloid goiter and restoration of normal basal metabolism has at times been followed by the establishment of normal menstruation. Functional dysmenorrhea has not been especially studied but relief was noted occasionally after the use of thyroid extract in hypothyroid cases with other predominating symptoms.

Thyroid surgery has contributed only a small percentage of the cases of hypothyroidism. Remarkable physiological adaptation is shown in that the varying amounts of remaining thyroid tissue function within normal limits in a good percentage of cases with only infrequently the development of hypothyroidism. It would seem that as a rule the tendency has been to take out insufficient thyroid tissue rather than an excess, although that tendency is becoming less and less. and increase in postoperative hypothyroidism may occur. Marked asthenia with low basal metabolism after thyroidectomy has been noted in one case, G. B., a female, aged 20, that did not respond to the use of thyroid extract. Analysis of this case showed inanition rather than overweight, without other signs of thyroid deficiency, and suggested that undernutrition was the basis of the reduced metabolism rather than postoperative thyroid deficiency.

An extreme example of changed nutritional state after thyroidectomy is that of A. R., a female, aged 20, who within one year gained 70 pounds in weight with, however, reduction after

proper diet and thyroid extract administration. A distinct change in the nutritional state of the individual with weight gain without changed diet or habits, combined with diminished basal metabolism, has not infrequently been the indication for the use of thyroid extract. It seems rather paradoxical that of two individuals with weight loss one may show reduced and the other elevated metabolism. Its basis exists in the first instance in the depression of metabolism secondary to inanition; in the second instance to weight loss secondary to the accelerated metabolism characteristic of exophthalmic goiter.

Of interest in psychiatry, one case, D. B., a female, aged 21, with narcolepsy is included in this series, if in that category may be included persistent and repeated somnolence without regard to the appropriateness of the procedure, making effective work impossible. Thyroid extract proved effective in this case. Another similar case[6] with response to thyroid therapy has been called to the writer's attention. Not infrequently vertigo has been noted—also irritability and impairment of memory.

In the study of underweight children at Lymanhurst School by the writer[7] there was a tendency for the basal metabolism to be below the average normal. Indeed to the pediatrician who is interested in the basal metabolism of children with nutritional or endocrine disturbance, this study at Lymanhurst and others[8] indicate that undernutrition tends to decrease basal metabolism and that the overweight child usually has normal basal metabolism. Of course, the above tenet would not hold in the unusual condition in children when exophthalmic goiter is the basis of the underweight. Indeed, in pediatrics especial care should be taken in the interpretation of the reported basal metabolism. In the first place, normal standards available vary appreciably; in the second place, inanition not due to any thyroid or other glandular dyscrasia is associated with reduced basal metabolism; in the third place, the overweight child has been found generally to have a normal basal metabolism. Only comparatively seldom in children has thyroid deficiency been demonstrated as the cause of overweight.

From the standpoint of internal medicine, the problem of unexplained secondary anemia has sometimes had its solution suggested by the discovery of diminished thyroid activity. Response to treatment has been noted only after the combination of thyroid extract with other anti-anemia therapy. In this connection it should be noted that according to Lusk[9] the general oxidation of the body is normally maintained in anemia provided the disturbances are not of extreme intensity. In pernicious anemia, when the hemoglobin falls to 20 per cent of normal, the basal metabolism is increased. Secondary anemia deserves study from the standpoint of thyroid function. Case J. V., a female, aged 28, with hemoglobin of 35 and basal metabolism of minus 16 per cent showed marked improvement of anemia after thyroid extract and iron.

Likewise, in that ever present group, chiefly of women, with a low level of energy output, asthenia and weakness, the symptoms are occasionally associated with hypothyroidism. Weakness in the cases studied has been a universal symptom and the only one common to all cases. As a direct symptom of reduced metabolism, increased sensitivity to cold has been of value; heavy clothes and the summer season are appreciated by the individuals with reduced oxidative processes. M. C., a male aged 42, whose basal metabolic rate was minus 13 per cent and whose systolic blood pressure was 104 mms. of Hg. showed definite improvement of rather incapacitating weakness after taking thyroid extract. Attention should be called to the fact that the basal metabolism is usually normal in obesity and that gain in weight is more commonly exogenous than endogenous. The luxus consumption or adaptation of the body to an increased metabolism after a large influx of food finally wanes and storage of fat occurs. The increase in weight noted occasionally after lactation has more basis in over-ingestion of food and changed habits of exercise than in lag in thyroid function. Obesity as in cases M. M., female aged 38; C. R. C., female aged 23; W. W., female aged 31; associated with low basal metabolism, responded well to dietary restriction aided by thyroid extract. M. C., a female aged 22, showed a weight 125 per cent of standard on an apparently low calorie intake. Weight gain not due to increased food suggested an endogenous origin although the basal metabolic rate was only minus 4 per cent. The use of thyroid extract was followed by appreciable weight loss and disappearance of unnatural drowsiness.

Of special interest has been the group with colloid goiter associated with diminished basal metabolism (females in the post-adolescent period and also in the third decade of life); cases M. W., aged 17; M. R., aged 25; D. N., aged 21; E. T., aged 28; R. F., aged 24; E. B., aged 21; and A. P., aged 21. Symptoms have been chiefly lack of energy, weakness, and menstrual disorders. Thyroid extract tended to increase the physical efficiency of this group very distinctly; occasionally reduction in the size of the goiter was noted. Some of these individuals have not known vigorous health until check-up for colloid goiter with reduced basal metabolism indicated thyroid therapy. It may also be noted that such therapy became unnecessary after its use for a few months in one case (M. R., aged 25).

The basal metabolic rates have varied from minus 12 to minus 29 except in two cases minus 7 and 4 per cent. Rarely the diagnosis of thyroid lag has been made from the clinical features without reduction of the basal metabolism below the lower limits of normal. It may be assumed that such an individual's normal metabolism had previously been above the average normal limits and that there was actual lowering of metabolism. From the technical standpoint it should be mentioned that, with the apparatus now commonly in use, errors may occur on the minus side, although, if the patient's condition is not basal, the results will be above normal. With the common clinical usage of apparatus measuring oxygen consumption, the technical simplicity should not lead physicians to disregard errors that give inaccurate low results as well as abnormally high results. Leaks about attachments, ineffective valves, and inefficient absorption with soda lime may give inaccurate low results.

The dosage of thyroid extract, Armour's preparation, employed has seldom been less than 1 grain daily and at times given every other day. The amount has been controlled by clinical course and by the basal metabolism with chief emphasis upon the condition of the patient. Serial determinations of the basal metabolism have been of value in determining the dosage. But no common standard at which to maintain metabolism was set for all cases. Rather it was attempted to determine the level for each individual case.

In conclusion it may be stated that hypothyroidism challenges interest and attention in the limited fields of medical practice and illustrates the universality of physiologic processes. The specific conditions cited in this series of cases with hypothyroidism are alopecia, thinning of hair, abnormal skin pigmentation, sterility, dysmenorrhea and amenorrhea, narcolepsy, asthenia and lethargy, secondary anemia, obesity, asthenia and colloid goiter. In these conditions of changed functions and sometimes of changed structure, study should include the thyroid status, which if sub-normal gives gratifying response to the use of thyroid extract. Attention is also called to technical errors giving rise to false low reports and also to other factors, chiefly inanition, giving rise to reduced basal metabolism unassociated primarily with thyroid disease.

TIBIAL FRACTURES INTO THE KNEE JOINT*

ARTHUR N. COLLINS, A.B., M.D., F.A.C.S.
Duluth, Minnesota

DESPITE the fact that the knee-joint is the largest joint in the body and that it has a multiplicity of ligaments entering into its structural support, it is still one of the weakest joints. Its vulnerability to attack by extrinsic forces as well as by intrinsic or perhaps torsion forces, places this complex joint in a most interesting light from the standpoint of trauma.

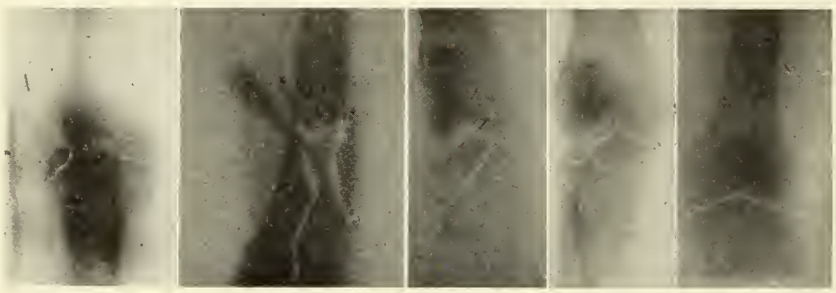
That the tibia receives a large share of the fractures of the lower extremity is well known and while fracture of the upper end of this bone is less common than of the lower end it is nevertheless serious in proportion to joint involvement. In Hartman's review of 335 cases of fracture of the leg, according to Barbilian, thirty-one were of the tibia alone and thirteen were of the upper end of the tibia (3.8 per cent), a much less frequent occurrence therefore than fractures of the other segments of the same bone.

The subject matter of the present discussion will be confined to a consideration of fractures at the upper end of the tibia, the fracture line entering the joint, or, as the French writers express it, fractures of the tibial plateau.

The range is extensive, from the simple one-line fracture, to that of comminution and many lines entering the joint; the fracture may also be compound. Now and then dislocation may be superimposed, though there were no dislocations in this series.

Twenty cases are herein presented, accumulated from the case records at St. Luke's Hospital, the fractures having been treated by other members of the staff and myself during the past four or five years. I wish here to acknowledge the courtesy and coöperation of those staff members who have aided me in this study.

Case 1.—A housewife, aged 68, while running for a streetcar, slipped on the ice and fell forward, striking her right knee. She was unable to walk. On examination she was found to have a comminuted fracture of the right tibia at its upper end, a wedge shaped fragment involving 85 per cent of the articular surface being displaced inward and downward but with the alignment fairly satisfactory. Reduction was effected and plaster cast applied. *X*-ray showed some improvement in the position of the fragment. Her convalescence was uncomfortable. She had continuous aches and pains in her right knee. However, she was up in a wheel chair on the ninth day and on the nineteenth day the record shows she was having less pain. On the twenty-fifth day the plaster dressing was replaced and on the twenty-sixth day she was discharged. The follow-up record shows that four months after the injury she was walking with a crutch and that she had dull pain in the knee, ankle and foot. She was bending the knee to about 50 per cent of the normal but was not yet doing her housework. She was using hot packs and massage for treatment.



Case 2.—A man, aged 53, a collector by occupation, was knocked down by an automobile and was brought to the hospital in shock. Examination revealed a comminuted fracture of right tibia and fibula; also a fracture of left leg below the knee and a fracture at the left wrist. *X*-ray showed a comminuted fracture four inches below the knee joint with the fracture line running upward into the joint, slight displacement but perfect alignment. Supportive treatment only could be given on account of shock, and death occurred. Autopsy showed: (1) gangrene of the left foot; (2) cardiac hypertrophy (425 gms.); (3) passive congestion of the liver (2,300 gms).

Case 3.—A laborer, aged 37, while scuffling and in an intoxicated condition, sustained a fracture at the left knee. He was admitted twelve hours after injury. There was swelling around and effusion into the joint coupled with pain and inability to extend the knee; also tenderness over the medial proximal end of the tibia. *X*-ray showed incomplete fracture of the inner condyle of the left tibia starting above the condyle in the joint surface and running outward and downward but not reaching the outer border. There was no displacement. Treatment was not recorded and follow-up was not obtainable.

Case 4.—A housewife, aged 47, jumped from an automobile while it was in motion. *X*-ray showed a fracture of the outer condyle of the tibia of a compression type, i.e., a portion of the articular surface being pressed straight downward into the upper end of the tibia as though into a softer or pathologic area. Buck's extension was applied for three weeks and followed by a plaster dressing for three to four weeks. No motion was possible until removal of the plaster. The follow-up report three months later states the knee "is sore all the time"; she bends it very little and walking is difficult. Six months later there was a slight limp but no swelling although the knee was painful when she was fatigued. There was enough bending at the knee to allow going up steps but she found it difficult to go down.

*Read at the annual meeting of the Minnesota State Medical Association, St. Paul, Minn., May 13, 1929.

Case 5.—A woodsman, aged 21, received an injury to his right knee when a log rolled off a sleigh against his leg. He was admitted to the hospital complaining of pain and swelling in the right knee and inability to walk on the leg. *X*-ray showed a wedge shaped fracture at the internal corner of the right tibia about 1.5 inches in each direction. Displacement was slightly outward and upward and the fracture line involved the joint surface. Treatment was by means of a plaster cast reaching to the mid-thigh. He left the hospital on crutches in the fifth week. Follow-up was not obtainable.

Case 1 Case 2 Case 3 Case 4 Case 5

Case 6.—A housewife, aged 54, received an injury to her left knee in an auto accident (no details). *X*-ray showed a simple fracture through the upper part of the left tibia, the fracture line running obliquely upward and forward and entering the joint. The fragment was in perfect position. Treatment consisted of plaster encasement from the ankle to the groin. This was painful and the plaster was replaced. Crutches were allowed on the fourth week. The cast was removed in the sixth week. The follow-up three months later states there was knee stiffness, that the bending was about one-half normal but also that the swelling was troublesome and weight-bearing difficult.

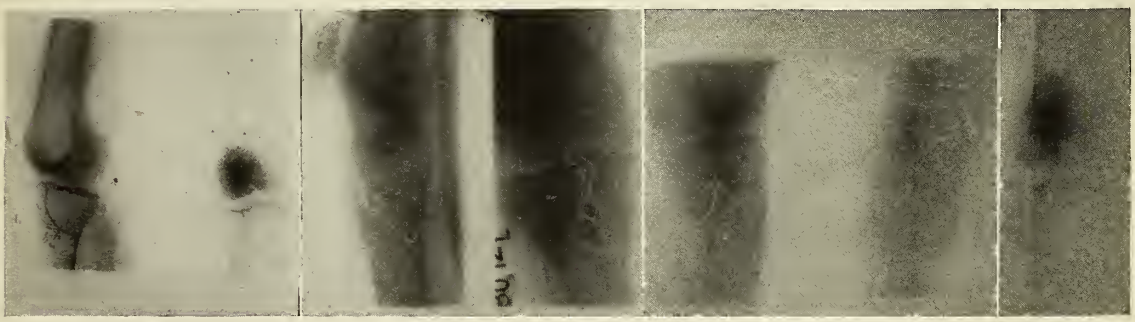
Case 7.—An attorney, aged 50, fell with his automobile over a forty-five foot embankment. He was admitted to the hospital with a compound comminuted fracture of the left tibia, at least five fracture lines running up and down through the upper end of the bone, one line entering the knee joint between the crucial ligament attachments. There was slight outward angulation. His treatment consisted of Buck's extension with weights and plaster casing on the thirteenth day. He was doing some weight bearing in the ninth week. A follow-up obtained four months later stated he had swelling and stiffness and some limping but was improving. Eight months later there was still some limping but no pain. There was some swelling when he was up and about. He could then bend the knee sufficiently to walk and was back to his work at the end of six months.

Case 8.—A janitor, aged 42, was knocked down by an auto, was run over and was picked up unconscious. On admission, there was no deformity but some swelling at the right knee. *X*-ray showed a comminuted fracture of the right tibia (also fibula). There was slight posterior angulation of the upper fragments of the tibia and the fracture line entered the joint. Incidentally there were also compression fractures of the seventh and eleventh dorsal vertebræ. Splints were applied at first and plaster dressing a week later. He was up in a chair in the eighth week and was then discharged. Follow-up report a year and a half later states there was some stiffness of the knee but no swelling. There was no bending for a year but at the time of the report he had about half normal flexion of the joint. He returned to work the fourth month after injury.

Case 9.—A landscape gardener, aged 63, fell off a ladder, injuring his left knee but was not admitted for *x*-ray until two weeks after the injury. At this time the *x*-ray showed a fracture of the outer condyle of the left tibia with the fracture line running upward into the joint. Callus formation was visible in the film and evidence of an hypertrophic arthritis. He was placed in plaster for five weeks and was allowed up on crutches in the fourth week. Follow-up records that two years later he was walking but had swelling in the knee and some pain and stiffness.

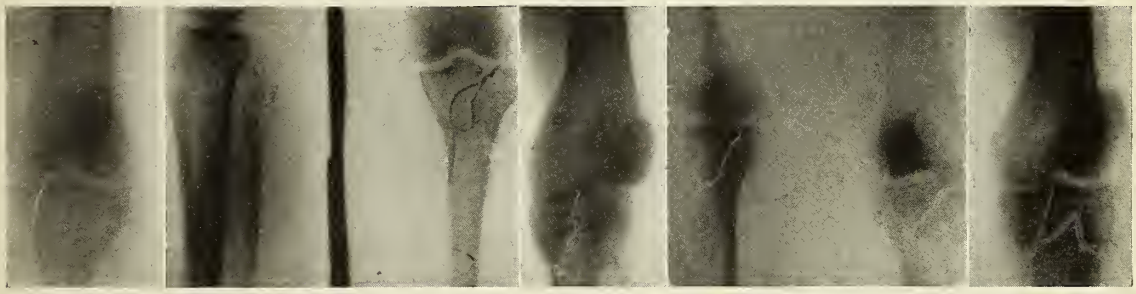
Case 10.—A watchman (formerly a blacksmith), aged 63, was struck by an automobile while crossing the street. *X*-ray showed a complete fracture of the internal tuberosity of the left tibia, the fracture line running into the joint. Reduction was done under general anesthesia and plaster applied. This was followed by distress from swelling and pain and a new cast was applied. He remained in the hospital nine days. The follow-up report obtained three and a half years later stated there was pain and swelling and stiffness and he was not able to work.

Case 11—A man, aged 59, was knocked down by an automobile. On admission, the *x*-ray showed a compound, comminuted fracture of the upper end of the right tibia, two of the fracture lines running into the joint. There was also a fracture of the left fibula. Reduction was done in two hours but an anatomical reposition was not obtained. The plaster case was removed on account of the poor position and Buck's extension and a Thomas splint with a fifteen pound weight were applied. Plaster dressing was delayed until the eighth week because of the open wound. He was on crutches by the fourteenth week and at that time was able to flex the knee to a right angle. He left the hospital at this time. A follow-up report four



years later stated there was stiffness but no swelling and that he has not worked since his accident.

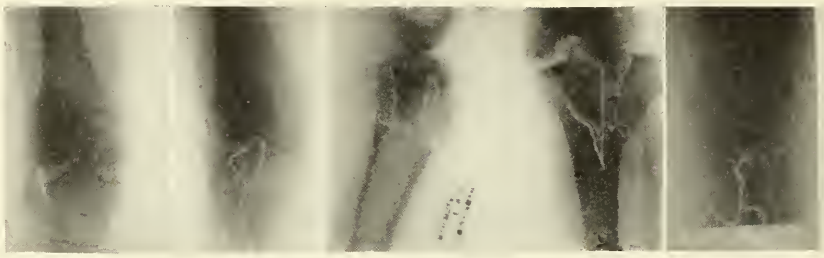
Case 12.—A man, aged 60, a clerk by occupation, was struck by an automobile and knocked against a fence, He was picked up unconscious, but consciousness had returned at the time of admission to the hospital. There had been no vomiting. There was loss of motion of the left leg and swelling at the left knee. *X*-ray showed a fracture of the left tibia just below the condyles. The fracture was complete and transverse; there was slight displacement and the fracture line ran upward into the joint. The leg was placed in a Thomas splint and on the tenth day a plaster cast was applied after gentle manipulation. Immobilization was maintained for eight weeks and he was then discharged, at which time flexion to 45 degrees was possible. He had moderate pain on motion. Follow-up was not obtainable.



Case 13.—A woodsman, aged 43, had his right leg struck by a swinging log. He was admitted to the hospital with swelling at the knee and effusion into the joint. *X*-ray showed a comminuted fracture of the upper end of the right tibia, the fracture line running upward into the joint. A Thomas splint was applied with extension and 45 degrees of elevation. A moulded plaster splint was applied on the third day. Slight bending to an angle of 15 or 20 degrees was allowed in the second week, and the leg was returned to its splint. The plaster was removed on the twenty-seventh day and crutches were allowed on the thirty-sixth day. Follow-up three months later states he had good anatomical and functional result. Five months later he had returned to work driving a team. Two years later he noticed no difference in function as compared with the uninjured knee. There was no limp, swelling or pain.

Case 14.—A blacksmith, aged 42, was kicked by a horse and thrown down while shoeing the animal. He was admitted with excessive swelling at the left knee and effusion into the joint. *X*-ray showed a comminuted fracture of the left tibia with the fracture line running into the joint. The fragments were fairly well related to each other. A Thomas splint was applied with extension and with 45 degrees of elevation. The ecchymosis gravitated into the thigh with compensatory reduction of swelling at the knee. A moulded plaster posterior splint was applied in the fourth week and crutches were allowed. The knee was bent under ether in the tenth week. Weight bearing was allowed in the ninth week. Follow-up report four months later stated the patient was walking without crutches; seven months later he had returned to work shoeing horses; eight years later he had good function, no limp but slight stiffness in the left knee. He had no swelling but there was slight pain if he straightened the leg quickly. He noticed an ache in bad weather and noticed the left leg tired more easily than the right. Motion was 50 per cent or better.

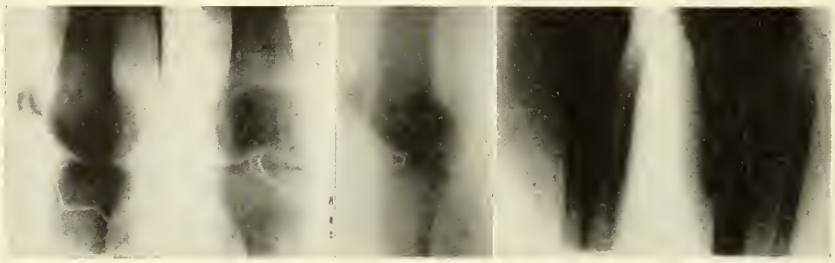
Case 15.—A clothes peddler, aged 72, was injured in an automobile accident, no details of which were given. *X*-ray examination on admission showed a wedge shaped fracture of the external condyle of the left tibia with displacement outward. His leg was placed in a Thomas splint with Buck's extension. Plaster dressing was applied on the fourth day. He was up in a wheel chair in the third week and the cast was re-



Case 6 Case 7 Case 8 Case 9

Case 10 Case 11 Case 12 Case 13 Case 14

moved in the fifth week. Crutches were allowed in the seventh week and at this time physiotherapy was begun. He was discharged in the eleventh week. Follow-up obtained a year later states he was walking; there was slight pain but no swelling and he had 75 per cent flexion. He was able to work in four months.



Case 16.—A housewife, aged 66, stepped out of an automobile, turned her ankle and fell, injuring her right knee. She was unable to walk and was admitted one hour later with much swelling at the right knee. *X*-ray showed an incomplete longitudinal fracture of the upper end of the right tibia with the fracture line extending downward from the joint for about an inch. There was no displacement of fragments. A plaster dressing was applied in three days but the knee continued to be painful and the cast was cut open and strapped together. She received massage beginning on the tenth day and was discharged from the hospital on the fifteenth day. A follow-up obtained two years later states that there was no trouble with the knee and that she was walking well.

Case 15 Case 16 Case 17 Case 18

Case 17.—A printer and dancing teacher, aged 29, was kicked down an embankment by a horse. He couldn't get up and was brought to the hospital two hours after injury to the left knee, where there was much swelling. *X*-ray showed a comminuted fracture of the upper end of the left tibia. The largest fragment consisted of the entire outer condyle, which was displaced outward. The smaller fragments lay between the outer and inner condyles and were in fairly good position. The entire upper end of the tibia was displaced outward. A Thomas splint was applied and extension with an eighteen pound weight. The leg was elevated on the splint to an angle of about 45 degrees to reduce the swelling at the knee. Plaster dressing was applied on the twelfth day and was bivalved. Motion was encouraged on the twenty-fourth day. The knee was bent under anesthesia in the seventh week. He was bending his knee to a right angle in the eighth week and was doing some weight bearing in the ninth week. Follow-up three years later states that motion is equal to that on the opposite side and that he won a dancing contest eight months after injury. He had no swelling or stiffness.

Case 18.—A housewife, aged 63, fell while standing on a stool. *X*-ray on admission showed fracture of the internal condyle of the upper end of the right tibia. The fragment was displaced upward and included both tubercles. The fracture line entered the joint. The leg remained in plaster dressing for five weeks, after which weight bearing was allowed. A follow-up obtained four years later stated that she walked without limp. For two years there was some pain, which, however, had disappeared. The joint was a little thicker but did not swell. There was some limitation of motion but she abandoned her crutches at three months and did light housework at six months after injury.

Case 19 Case 20

Case 19.—A laborer, aged 42, was knocked down by an automobile, which also ran over him. He received injuries to both knees and was admitted to the hospital in condition of disorientation and with mumbling speech. *X*-ray showed: (1) a fracture in the articular surface of the right tibia toward the inner side, the fragment being wedge shaped with the point inward and the fracture line entering the joint; (2) also a fracture involving the entire inner condyle of the left tibia. The fracture line began about 4 cm. below the joint and ran upward into the joint at the intercrural space. The fragment was in perfect position. Details of treatment not given except that he was getting about on crutches at the time of follow-up. The follow-up five months later stated the right leg functioned

normally. The left however caused him to limp and in this knee he had pain. He had swelling on this side also but an attack of typhoid earlier in his life, followed by phlebitis in the left leg, was regarded as a factor in causation of the swelling. Flexion at the left knee was limited to 45 degrees. He had not returned to work.

Case 20.—A man, aged 56, a clerk by occupation, fell from a ladder while working on a roof. He was admitted five hours later with swelling at the right knee and lateral hypermotility. *X*-ray showed a comminuted fracture of the upper end of the right tibia (also the fibula) with at least two or three fracture lines running upward into the joint. There was moderate separation of the fragments from the shaft of the tibia with a slight backward displacement and angulation. The leg was placed in a Thomas splint with Buck's extension and no weights. A Hawley pin was placed in the heel for skeletal traction. Anatomical position was satisfactory, the temperature was normal and there was no evidence of infection at the time of report. The patient was still in the hospital.

Of the causes producing these injuries, we see on tabulation that the automobile was responsible for eight of twenty (40 per cent). There was no other one cause which approximates this percentage, the next in line being 10 per cent, several different types of accidents producing this percentage.

TABLE I

Causes of Injury:	
1. Knocked down by auto	5
2. Auto accident (no details)	3
3. Struck by swinging log	2
4. Twisting injury	2
5. Kicked by horse	2
6. Fell from ladder	2
7. Fell from stool	1
8. Fell with auto from height	1
9. Jumped from height	1
10. Fell, striking knee	1

The injury is one quite evidently threatening those past forty years of age. In these twenty cases all but three were over forty years of age (85 per cent). Men, according to this group, are three times more likely to have the injury than women. There were fifteen men and only five women listed here.

TABLE II

Ages	42,	63,	29,	66,	72,	42,	43,	60,	59,	63,	63,	42,	50,	54,	21,	47,	37,	53,	68,	56
Sex	M	F	M	F	M	M	M	M	M	M	M	M	M	F	M	F	M	M	F	M
Right or left	RL	R	L	R	L	L	R	L	R	L	L	R	L	L	R	R	L	R	R	R

Both knees were about equally involved, inasmuch as ten of the injuries were of the right knee and nine of the left, while in one man, both knees were injured. This man with both tibiæ fractured into the joints, is, so far as I have been able to find, the only case of this type recorded to date.

None of the cases in this series were treated by open operation and it is a striking and important fact that there are no cases of non-union recorded nor to be found in the follow-ups. This is an interesting disclosure of fact and should afford those treating fractures at the upper end of the tibia courage in instituting early motion. The rich and plentiful blood supply in the cancellous tissue at the upper end of the tibia favors early union, and if the fracture is not compound little fear of infection need exist.

The following table gives in brief the result of treatment.

TABLE III

	Cases
Unclassified	6
Cases untraceable, dead, or still in hospital or under treatment.	
Poor	2
Fair	5
None of these cases received early motion.	
Good	7
Six of the seven cases in this group received early motion or manipulation or massage or all three. In two cases the knee joints were bent under anesthesia.	

There is undoubtedly significance in the fact that fractures in this region heal well. There has been no instance of non-union. Those cases treated by early motion, massage and manipulation have had the better results.

The Thomas splint is a convenient apparatus in which to transport the patient to the fluoroscopic table where comminuted fragments may be moulded into position. It may be employed in conjunction with Buck's extension.

Barbilian in a comprehensive article reported ten cases and summarized the French literature. The cases he reported were all over forty years of age. He calls attention to the age incidence, which is at a time when the bony elasticity begins to lessen. However, these fractures may be produced earlier in life. Tedenat reported a case occurring at eighteen years (Heidenreich). My cases were equally divided between men and women, whereas Grimbel found the occurrence almost three times as frequent in men as in women.

Barbilian states that fracture of one tuberosity is more frequent than fracture of both but is nevertheless rather rare. In 1916 Tanton could collect only sixty-three published cases. Fractures of the tibial plateau are only a variety. They are interesting on account of their gravity rather than on account of their frequency. Heidenreich in 1877 collected thirty-nine cases, this being the first complete and well founded work on these fractures of the upper end of the tibia and even today is a classic.

These fractures occur more frequently in winter because of the greater frequency of trauma. The internal tuberosity is a little more often involved, according to Sonntag; twice as frequent according to Bossi.

It is difficult to decide whether the lesion results from the shock produced in falling or from tearing by muscular contraction and pulling on the part of the ligaments. Fracture by direct blow is becoming more and more frequent, due to the greater speed of vehicles, which render trauma more frequent and more violent. Further, one may say that with advanced age one may think of an indirect mechanism, while the younger the individual the more one should consider direct trauma.

Direct fractures are produced by a blow at the superior extremity of the leg: the kick of a horse, crushing by the wheel of a vehicle, a fall down stairs, a fall on the bone itself, etc. In a fall, the instinctive tendency is to touch the ground first with the external side of the foot. This results in abduction of the knee, bringing the articulating surfaces of the internal side closer together; the greater impact is thus at this point.

Barbilian and his co-workers have never been able to obtain true fractures by simple internal or external torsion of the knee joint experimentally. Only small tears resulted in compact tissue. However, if to a certain degree of torsion or of lateral flexion there is added a direct blow at the level of the superior external side of the tibia a fracture could be produced. The force necessary is still much less when there is torsion. This proves that in exaggerated positions, the resistance of the bone is diminished. Without excluding entirely the mechanism of tearing we believe we must admit a mixed mechanism; direct and indirect at the same time.

Segons obtained fractures of the tibial plateau itself experimentally by simple forced extension in a subject with a rarefied osseous system.

Symptomatology: At the time of the accident the patient feels a very sharp pain but, felled by the blow, is not always conscious of the crepitation of the fractured bone. Functional impotence is added to the pain which every attempt at movement makes worse. The intra-articular effusion of blood infiltrates the soft parts, distends the knee, rising to mid-thigh and descending into the leg. Ecchymosis soon makes its appearance. Its site and limits may be very extensive, is variable, but the infiltration tends to descend and thus become more intense in the popliteal space. The coexistence of this popliteal ecchymosis and the articular swelling should then always indicate a fracture, either tibial or femoral. Deformity should also make one think of a grave lesion. The partial flexion of the leg on the thigh is observed in almost all cases. More important, but less frequent, is the deformity of valgus or varus, according as the external or the internal tuberosity is involved. The valgus knee is observed not only in almost all cases of fracture of the external tuberosity but also in those of the internal tuberosity. To these deformities may be added subluxation of the leg outward by the gliding inward of the femoral condyle and the external rotation of the leg. Relative shortening will occasionally occur.

A symptom which always exists, but which is more or less marked according to the degree of displacement of the fractured segment, is widening of the tibial plateau. This may be noticeable in the absence of effusion but difficult to make out in the presence of effusion. Palpation may permit one to localize the site of fracture. However, great effusion on one side and sharp pain on the other may render palpation very unreliable. A clear, painful line or a palpable groove may correspond to the fracture line in the bone. Mobility of a fragment may be palpated if its fibrous coat is torn. Barbilian states that crepitation is rare because the spongy tissue is unfavorable to its production.

X-rays should always be used to determine the variety of the lesion and to find out the relation of the fragments.

A severe sprain of the knee could be mistaken for a fracture of the tibial plateau; it could indeed present the grave signs of a fracture—intense pain, swelling, functional impotence; but

widening of the tibial plateau and popliteal ecchymosis associated with swelling will eliminate a diagnosis of sprain.

Prognosis: Fractures of the tibial plateau are grave fractures because they are articular. Loss of function in the knee, total or partial, is to be feared. In general, even in the most fortunate cases where complete integrity of function is restored, this is often not realized for a year and a half or two years.

Complications: The most formidable of complications is without question the occurrence of a compound fracture. Late complication is retardation of union which may end in false articulation. Among functional complications the most important is poor recovery of movement, which may amount to ankylosis. Articular function may be impeded by a deforming callus, by lateral motility or by a deformity. Rather often a chronic arthritis supervenes.

Treatment.—1. Orthopedic: This consists of (a) early evacuation of hemarthrosis; (b) reduction of fracture; (c) immobilization for a month; (d) massage and later, mobilization until complete recovery.

2. Surgical: reduction of fracture by arthrotomy through one of the classic procedures and maintenance of the reduced fragments by a definite fixation. Immobilization is of very short duration and is followed by massage and mobilization.

Surgical treatment has not proven the superior method. The spongy bone does not lend itself well to osteosynthesis. Moreover the general state of the patient often does not warrant any surgical procedure. Once accomplished the immediate results of surgical treatment are often more satisfactory but the end-results are not exempt from grievous consequences. Metallic prosthesis is not well tolerated in many cases and infection, which of all complications is to be avoided, may result. In some cases a second intervention is necessary for the removal of the metal.

Non-surgical treatment (orthopedic):

If a perfect anatomic restoration is not always realized by the orthopedic method, a satisfactory function is usually easily obtained.

If the orthopedic method is slower, it is surer.

Articular atrophy and stiffness accompanying the orthopedic method may be lessened, in large measure, by early massage and mobilization, with expectation of their ultimate disappearance.

Without eliminating surgical treatment Barbilian reserves it for cases where there is great displacement and serious ligamentary tears.

The cases in the Barbilian report show that very satisfactory recovery can be obtained by the orthopedic method and that this method involves less risk.

Desgouttes and Ricard report four cases treated by a simple reduction and immobilization in the cast; results being as good as those obtained by other methods. These writers insist on the fact that the two tuberosities of the tibia have very unequal importance in the equilibrium of the knee, the role of the internal being more important. Fracture of the internal even with slight displacement will be grave, whereas fracture of the external, even accompanied by great displacement, will react but little on articular equilibrium.

These writers urge more frequent use of a simple cast without abandoning necessary surgical means, but they state we hope to accomplish too much by surgery. After-results, which *x*-rays and examination of the patient do not permit us to hope for, are obtained by simple immobilization.

Dehelly presents a case to show the use of the bone graft and to call attention to immoiblization of the leg in flexion in fractures of articulating extremities. He uses partial flexion more and more and regards the results as to mobility as excellent. He feels that when the leg is immobilized in extension almost complete rigidity of the knee often results.

Swete-Evans reports a case of tibial fracture occurring in a private twenty-four years old who while playing Soccer fell with knee bent as his opponent sprang up and came down on the outer side of the patient's thigh just above the knee. The *x*-ray showed a vertical T-fracture from the knee joint on the outer side of the crucial ligaments three to four inches down the shaft of tibia with pieces of bone and semilunar cartilage or meniscus wedged in the fissure. Treatment was surgical. Arthrotomy was performed and blood and mashed bone expressed; screws were inserted; a McIntyre splint applied; postoperative shock occurred, but recovery. Progress for one year, satisfactory: "will be able to return to military duty."

Cubbins, Conley and Seiffert report two cases of fractures of the lateral tuberosity, the fragments widely heparated and the meniscus separated from its lateral attachment and displaced downward between the fragments. Open operation was necessary in order to dislodge the meniscus and approximate the fragments. The meniscus was sutured back in place. Careful passive motion was begun in two to four weeks. A removable cast was used as support for eight weeks.

Moreau reports twenty-two cases: nine of fracture of the external condyle, two of the internal, five of both condyles and four gunshot fractures of the external and two of the internal condyle. The symptoms were dominated by hemarthrosis and swelling; suffusion of the limb was not a constant sign. Crepitation and abnormal mobility of the fragment were usually absent. There was absolute functional impairment and weight-bearing was impossible. Joint-puncture was usually employed and sometimes repeated. In one case Willems treatment was instituted. All cases were immobilized in splint or plaster. After a number of days, varying with the joint, massage and active exercises were added. Results: two very good results, without valgus deformity, good motion two months after puncture, compression bandage, continued traction. Two excellent results after one month from puncture and Willems treatment. After simple immobilization; one normal, one satisfactory functional result with slight and moderate genu valgus; three very good functional results without deformity. In five cases of fracture of both condyles, plaster immobilization without puncture; in two cases traction was applied. Results were satisfactory though not so good as single condyle fracture.

SUMMARY

In this serious type of fracture the automobile is responsible in twenty cases for 40 per cent of the injuries and in ten other cases for 30 per cent, an average of 36 per cent. The injury occurs chiefly in men forty years of age or over. Barbilian has shown that a combination of torsion and direct trauma are for the most part responsible for this type of injury.

Two cases of sunken or compression fracture are recorded; one of the writer's series of cases and one reported by Dehelly.

Two cases of spreading or T-fracture with a semilunar cartilage or meniscus wedged in the fissure are recorded; one by Swete-Evans and one by Cubbins and his associates.

Some writers insist that the internal tuberosity is the more important from a functional standpoint and should be conserved more cautiously than the external.

Barbilian mentions delayed union or non-union as a late complication, but the writer finds no reports of this nature and is inclined to believe, on the contrary, that these fractures heal well, owing to the cancellous bone and rich blood supply.

Early motion in a series of twenty cases is seen to be coincident with the best results, judging by the follow-up reports.

Surgical treatment is reserved for the occasional or exceptional case of gross deformity and ligamentary tears.

The weight of opinion leans to conservative or orthopedic treatment rather than surgical intervention. While a perfect anatomic restoration of position is not always realized by the closed method, and while it may be slower, it is surer.

The writer wishes to emphasize in the closed method:

1. Elevation of the extended leg to a sharp angle (30 to 45 degrees) to rapidly reduce swelling at the knee.
2. Puncture if excessive intra-articular effusion.
3. Buck's extension on Thomas splint.
4. Massage after the first week.
5. Early motion second to fourth week.
6. Removable plaster during the third or fourth week for support and to facilitate treatment.

EXPERIENCES IN THE USE OF THE SULPHOCYANATES*

Joseph F. Borg, M.D.
Saint Paul

In recent years there has been decreasing in the medical mind the feeling that hypertension be considered a phenomenon compensatory to structural vascular change, and there has been an increasing knowledge of factors suggesting that it is a primary result of an unknown cause, producing a variety of degenerative changes. Thus Moschowitz[1] has recently strikingly pointed out the relation of arteriosclerosis to increased vascular tension, and the secondary kidney and cardiac results of this condition challenge us to search for measures to combat its underlying cause. While the etiology of hypertension is still unknown, the arteriolar spasm associated with it is well recognized as being for a long period its immediate inciting cause (the etiology of spasm being still undetermined), and the wide search for remedies has resulted in the study of a number of drugs, from the long known nitrites to the recently tried watermelon seed extract, most of which probably act by relief of vascular spasm, with varying results. These observations make evident the encouraging results possible in this form of therapy, the rationale of which is seen in the probable postponement of the secondary cardiovascular and renal complications which are so often the first to call the patient's attention to his condition.

Of the many drugs used, the sulphocyanates were first found to be effective in this condition in 1903 by Paul,[2] who in experiments comparing the action of iodides with these drugs noted the reduction of blood pressure obtained and used it with success clinically. There appears little further in the literature regarding this therapy until 1924, when Westphal[3] called attention to rather remarkable results which he was obtaining with it, only three of thirty-five cases resisting treatment. Since then it has been fairly extensively used in Europe, with few reports from this country. Nichols[4] has given it a thorough study and extensive clinical trial with excellent results. Kramer,[5] Gager,[6] Palmer and Sprague,[7] and Logefiel[8] have reported results chiefly favorable. It was with these in mind that we decided to give the drug a trial on our Ancker Hospital and Dispensary services, and this report covers our experiences with its use in twenty-four cases. It is not with the purpose of drawing definite conclusions from so small a series that this is presented, but rather with the hope of demonstrating the effectiveness of the drug in reducing blood pressure, and especially to point out the variable dosage necessary in different individuals to obtain a result and the possible unfavorable side effects associated therewith.

In this group were eighteen women and six men, ranging from fourteen to seventy-five years of age, with no significant variation in result associated with either factor. There were sixteen dispensary patients and eight hospital patients, the latter, even though ambulatory, securing an average systolic drop of 8 mm. Hg. more than the former, this difference, however, being eliminated after the patients left the hospital.

Following the recommendation of Nichols, backed by an extensive trial, we decided to use the sodium salt, although it was necessary with the first few patients to use the potassium salt with which many had gotten excellent results. Hospital patients were kept in bed about one week and all were given sodium bromide for at least this period to effect any sedative action possible in reducing the pressure. Dispensary patients were permitted to rest ten minutes in the dorsal position before the pressure was taken. Pressures to be given are the averages of at least four consecutive readings with comparatively short intervals between them.

In accordance with Nichols' experience, and contrary to the advice of others, we started with a five grain dose three times daily, but in four of five patients untoward side effects necessitated discontinuance of the drug. Later patients were started on two grain doses, and if no result was obtained in a week to ten days, were given increasing doses, the largest being ten grains. The medicine was continued one to four weeks after a maximal drop was obtained. Four patients were given the potassium salt, eighteen the sodium salt, and two received both salts on sep-

*Presented before the Minnesota Society of Internal Medicine, St. Paul, November, 1929.

arate occasions, without any noted difference in the results obtained.

Twenty-two, or 92 per cent of our patients, showed systolic pressure drops varying from 15 to 150 mg. Hg. with the majority obtaining very substantial reductions, the largest group of patients being the seven who showed 50 to 60 mm. drops. Fifteen, or 62.5 per cent, showed diastolic reductions, usually above 20 mm., the greatest being in our youngest patient, where a drop of 100 mm. was obtained.

Only two of the groups failed to show an average systolic pressure reduction, one of these being a tertiary luetic who later developed a substantial reduction on specific therapy, and the other a man with severe kidney damage who could not tolerate our minimal dose. Nine cases, however, had no average diastolic reduction, and there were no particular factors with which this could be associated.

The maximal drop in pressure was recorded at varying times after starting the drug in different individuals, some showing it at three days, others requiring a month, the average being about two weeks. Those requiring the longer time usually took larger doses, the step-up in dosage being made at seven to ten day intervals. Once the pressure was being held down for about a week the drug was discontinued and the lowered pressure was found to persist from a few days to two months. Those who were followed sufficiently long were usually found to respond again on resuming medication. When a result was being obtained it was noted that overexertion, and domestic, economic and other worry would cause sharp temporary rises in pressure in spite of the medication, a rather frequent situation in the class of patients studied, and it emphasized the importance of the psychic factor and the difficulty in obtaining results where uncontrolled.

Twelve of the twenty-four patients complained of symptoms associated with hypertension, chiefly headache, vertigo, tinnitus, weakness, dyspnea, and abdominal distress. Of these, six were completely relieved of severe headache, five had marked relief and one no relief. This relief, when obtained, was obtained within the first ten days, further medication failing to enhance it.

On the other hand, thirteen developed unpleasant complications. Of these, eight complained of marked weakness, chiefly of the legs and arms; some had vertigo. With the onset of such symptoms the drug was discontinued, and after a few days all were relieved of these effects which had been produced on dosages varying from two to ten grains t.i.d.; only one, however, on the minimal amount. This experience was in accord with that of others, but far more striking. One patient developed a severe distressing erythema with intolerable itching which persisted about ten days after the drug was stopped but there was no desquamation as in the only similar case found in literature, that reported by Weis and Ruedeman.[9] It suggested very much the early form of lesion seen in dermatitis exfoliativum. Most disturbing, however, was the development of toxic psychoses in four patients, with disorientation, hallucinations of sight and hearing, mania, confusion, and ideas of persecution, singly or in combination. Such diagnoses were verified by psychiatric consultation. These caused considerable concern when they appeared, but they lasted only five to seven days after the drug was stopped. They were all in patients to whom it had been necessary to give from seven to ten grains t.i.d. to obtain a desirable reduction, and it is to be noted that as a group they showed the greatest lowering of pressure of the series. It was interesting also that this group maintained a considerably longer period of lowered tension after the cessation of symptoms, without medication, than the rest, all being much more comfortable and free from symptoms for three weeks or longer. These manifestations were always preceded by complaints of weakness, but excepting in one case, were in hospital patients, resting a great part of the time and calling little attention to it. The ambulatory case was one of our first patients in whom we were not certain at first as to the significance of the weakness, the later experience with which made us proceed more cautiously with the drug.

Retinal examination was made in over half the cases, all showing moderate degrees of arteriolosclerosis, and two with hemorrhages and exudates, but there was no relation between these findings and the results obtained.

Urinary examinations were all negative except of one elderly patient with much albumin and many casts and pus cells, who later came to autopsy revealing an old extensive urinary tract infection. Phenolsulphonephthalein tests were performed on twelve of the twenty-four cases with greater than forty per cent elimination in two hours in ten cases. In these there

was no constant relation to the degree of response, practically all having marked pressure reduction. Of the other two, one case with no elimination of the dye in two hours obtained no pressure reduction, and the other with a twelve per cent two hour elimination secured a systolic reduction of 50 mm. Hg. and no diastolic reduction. Obviously there was insufficiently advanced renal impairment in this series to draw any conclusions as to a relation between renal function or urinary tests and the result to be expected, although a substantial reduction was obtained in two cases with undoubted advanced renal damage.

Blood examination revealed a moderate secondary anemia in four cases, all of which responded to the sulphocyanate therapy. One patient who obtained no result from the drug had a positive Wassermann reaction and later obtained a drop of 30 mm. Hg. systolic, 18 mm. Hg. diastolic on mercury salicylate medication.

Blood chemistry examination in thirteen patients gave normal values except in one instance, this being a girl of fourteen years, who showed the largest drop in pressure of the series. She showed a urea of 34.3 mg. per 100 c.c., which was reduced under therapy to 26.6 mg., with a corresponding improvement in phenolsulphonephthalein excretion from 34 to 55 per cent in two hours.

Electrocardiograms were done on all patients, fifteen of the twenty-four showing evidences of myocardial damage as shown by T-wave inversion, arborization defects, P-wave abnormalities and arrhythmias, but study revealed no relation of these signs to results obtained from sulphocyanate therapy.

Our experience with the youngest patient, a girl of fourteen years, was sufficiently interesting to warrant a short summary. This child, anemic, markedly emaciated, weighing fifty pounds, was admitted to the hospital complaining of weakness and vaginal hemorrhage, which she had considered the beginning of her menstrual periods, a loss of weight of ten pounds, and failing vision. She also had dyspnea on moderate exertion, nocturia, and headaches of about seven years duration. Examination revealed a moderate cardiac enlargement, low palpable kidneys, marked arteriolosclerotic retinæ with hemorrhages and exudate, markedly sclerosed and tortuous radial and brachial arteries, and a blood pressure of 252 systolic, 180 diastolic. She was found to have no vaginal hemorrhage, a normal pelvis, and a markedly bloody urine. Cystoscopic examination showed the blood to be coming from the left ureter, which was shown by the pyelogram to be greatly dilated, and capped by a bifid pelvis with irregularity of the minor calyces. Repeated observation by urologic consultants failed to bring out a diagnosis of the renal condition. After an initial period of observation she was put on sodium sulphocyanate, five grains three times daily. Within the next ten days she had an initial drop of 80 mm. systolic, 65 mm. diastolic, pressure and the hematuria stopped. This dose was kept up three weeks with marked improvement, the patient feeling well. Hoping to further reduce the pressure, the dosage was increased to 7.5, then to 10 grains, on which she soon developed a convulsion, followed after two days by a toxic psychosis which lasted four days. Associated with this she had an additional drop of 70 mm. systolic, 35 mm. diastolic, which persisted after the clearing of mental symptoms, without medication, which was stopped at the time of the convulsion, during the following month, after which she was discharged, having shown a marked improvement in the anemia, a gain of twenty-seven pounds in weight and having no complaints whatever. We have been unable to follow her since but have learned indirectly that she has had a mastoid operation recently and that her pressure is now back to 200 systolic, it being five months since her discharge. She has had no sulphocyanate since that time.

The other patients developing a psychosis, adults of middle age, two women and one man, all had premonitory weakness preceding the mental symptoms which persisted five to ten days. These patients had systolic reductions of 53, 55, and 55 mm. respectively, and diastolic reductions of 22, 23, and 28 mm. respectively, persisting three, six, and six weeks after the relief of the psychosis. These were the only patients receiving a maximum of five grains, in which cases no psychosis developed.

DISCUSSION

This small series of cases has been of interest to us because it has represented the panorama of development in our knowledge of the sulphocyanates. It has revealed that the drug produced a definite drop in systolic pressure in 92 per cent of the cases, and in diastolic pressure in 62

per cent. Concomitantly it reveals that these drops are not to be obtained without the risk of unpleasant side effects if the drug is to be used in effective dosage. On six grains daily ten of twelve patients secured an average reduction of 30 mm. systolic (only five securing diastolic reductions, averaging 14 mm.). Of these, four developed marked weakness, showing that even with minimal dosage the drug is not without unpleasant side effects. These increase as the dosage is increased, all patients receiving over five grains t.i.d. being affected, with a very real danger of developing a toxic psychosis, which occurred in four of five such patients. It is not possible to say to what degree the possibility of cumulative effects of the drug may enter into the explanation of these symptoms, as no studies of excretion were made, but these observations are very suggestive of it. However, the rapid improvement of those developing toxic psychoses together with the long periods of maintained pressure reduction suggest that some other factor may explain its prolonged effect. The psychoses were quite alarming, being preceded and accompanied by a marked degree of weakness. However, their duration was not long and unusually good results followed in the reduction of blood pressure and general improvement in the patients' condition.

CONCLUSIONS

Recognizing the futility of drawing conclusions from a small observation experience, the following may be better presented as supported impressions.

1. The sulphocyanates are effective in a high percentage of cases in reducing blood pressure.

2. The majority of patients will secure a reduction of pressure on minimal dosage, 6 grains daily, a greater lowering of pressure being obtained by increasing the dosage, but only by raising the risk of securing unpleasant side effects; larger doses, therefore, must be used with extreme caution.

3. Side effects manifest themselves in weakness and dizziness progressing to symptoms of psychosis, as disorientation, hallucinations of sight and hearing, ideas of persecution, and mania.

4. These side effects do not long persist after the drug has been stopped, and leave no after-results.

5. Patients developing side effects on the whole receive more satisfactory pressure reductions than those who do not.

6. More than 90 per cent of patients having symptoms probably caused by hypertension are completely or markedly relieved by sulphocyanates.

7. The lowering of blood pressure effected by sulphocyanates persists considerable periods of time, up to two months after the drug is stopped, and is explained either by cumulative effects of the drug, or, more likely, some persistent effect on vascular tone.

8. Factors of sex, age, retinal pathology, urinary findings and tests, myocardial damage as shown by the electrocardiogram, heart size or outline as shown by the *x*-ray, and blood examination as to chemistry, and cytologic and serologic tests revealed no relation to the result obtained which would influence therapy or expected response at all.

9. It is to be emphasized that while the sulphocyanates are efficient drugs to be considered in the treatment of hypertension, they should only be employed where the patient is under sufficient observation so that the administration may be easily controlled, realizing the possibilities of unpleasant side effects which attend its use.

PERNICIOUS ANEMIA IN THE YOUNG*

KARL W. ANDERSON, M.D.
Minneapolis

THE occurrence of pernicious anemia during childhood or infancy is perhaps worthy of renewed discussion for reasons other than statistical curiosity. As a result of the intensified studies which have followed the discovery by Minot and Murphy, it is becoming clearer that blood morphology in obscure cases, even when studied by experienced morphologists, is not sufficient for the differentiation between pernicious anemias and anemias of other types. This statement is supported by the views held by Downey,[2] that the red blood cells alone present no pathognostic morphological picture in pernicious anemia. This apparently is particularly true of anemias during early ages. Further, it is clear that the presence of a well established achlorhydria (histamine test) does not help in the differential diagnosis since achlorhydria is frequently found even in cases of unquestionable hypochromatic anemias. This, of course, does not alter the fact that a diagnosis of pernicious anemia with a persistent gastric secretion of hydrochloric acid might be doubted. Further, it is possible to state that positive response to liver extract therapy is not diagnostic of pernicious anemia. This again does not affect the opinion held by Minot[5] that the diagnosis of pernicious anemia should be looked upon with doubt in any case in which there is no favorable response to massive and prolonged treatment with potent liver extract. Thus, in some cases, the diagnosis of pernicious anemia at the present time seems so difficult that one is inclined in the last analysis to rely on the presence of a typical combined degeneration of the ascending and descending tracts of the spinal cord for a definite diagnosis. This statement is hardly modified, but rather supported by the well known existence of cases where the cord changes precede the anemia by several years or the anemia never develops. Somewhat at variance with this view is the standpoint taken by Naegeli[4] and Downey,[2] who feel convinced that certain characteristic changes in the arrangement of the lobules or the chromatin and in the granulation of the neutrophilic leukocytes occur with sufficient regularity to make the "pernicious anemia neutrophil" the most valuable single symptom for the diagnosis of pernicious anemia.

Viewing the question of the occurrence of pernicious anemia during infancy and childhood in this light, considerable difficulties arise. The following viewpoint might well be drawn into the consideration in this connection. The familial occurrence of pernicious anemia has been well established, possibly to a degree sufficient to suggest an hereditary factor. One might well expect this hereditary factor to be more marked, or at least sometimes present in cases reported as pernicious anemia in early life. This factor does not seem to have been taken into consideration in the reported cases of pernicious anemia in the young.

It is evident that some of the cases reported in the literature of fatally ending anemias in childhood presented a blood picture identical or closely resembling the blood picture in pernicious anemia. To this group belong the cases described by:

1. *Hotz.*[3]—The case of Anna K., aged 11, whose principal complaints were weakness, increasing pallor, anorexia, diarrhea, abdominal pain, occasional fever. She was well developed, well nourished, but did not have the characteristic lemon-yellow hue to the skin. She went progressively downhill until her hemoglobin was around 30 per cent and red blood cells 1,320,000. By the use of a diet and iron injections, she had a remission in which her blood apparently became normal. This condition lasted for six months; then, without any response to therapy, she went again downhill, developed bronchopneumonia, and died. No examination of the gastric juice was made, and no neurological findings suggestive of subacute combined degeneration were noted, but the blood presented a red cell picture which was described by the author as indistinguishable from pernicious anemia.

2. *Von Seth.*[6]—A fifteen year old boy, who complained of weakness, pallor, marked dyspnea,

*From the Medical Service, University Hospital, Minneapolis, Minn.

and slight general anasarca. For seven months his blood went up and down, but never reached normal, with anasarca increasing in amount. His red count was 650,000, hemoglobin 12 per cent, leukocytes 2,500. He died, and postmortem examination revealed red bone marrow, an enlarged spleen and liver with marked hemosiderosis, dilated heart with normal valves, and bilateral pleurisy.

3. *Andrew Barr.*[1]—A sixteen year old boy, who was well developed and well nourished. He complained of progressive weakness of three months duration with increasing pallor of the skin for five months, and, when admitted to the hospital, had a distinct lemon-yellow color of the skin. The subcutaneous fat was well preserved. Never on admission or throughout his illness was glossitis present. He had an achlorhydria, and he ran a slight fever. On admission his blood showed 770,000 red blood cells, 5,600 white blood cells and hemoglobin 22 per cent. Five weeks after admission his red blood cells were 420,000 with a hemoglobin of 10 per cent. Three months after admission he rallied and improved to the extent of 850,000 red bood cells and 23 per cent hemoglobin. This improvement did not continue more than twelve days when he took a sudden turn for the worse and died. No postmortem examination was done.

4. *Zuzki*[5] *of the Department of Pediatrics, University of Kyoto.*—A case in a nine year old child which was impossible to differentiate from a typical pernicious anemia. The clinical course of this case was progressively downhill to a fatal outcome. The red blood cells showed polychromasia, anisocytosis and poikilocytosis, and there were megaloblasts and normoblasts present in the blood smear. Although there was no remission in this case, the presence of normoblasts speaks against the diagnosis of aplastic anemia. This case is of particular interest in view of the fact that pernicious anemia is extremely rare, if at all present, in the Japanese and Chinese races. From the clinical course, it is doubtful whether this was a case of pernicious anemia, but from the morphological red cell picture, it would not be possible to differentiate from the true pernicious type of anemia.

It is worthy of notice that the clinical picture in these cases is incompletely recorded and that the course of the disease presents certain deviations from the ordinary picture of pernicious anemia. One only had a characteristic remission; one only had a characteristic lemon-yellow skin; achlorhydria was mentioned once. In but one of the cases is there any mention of a neurological examination. There is only one account of postmortem examination.

To sum up: There are certain cases in the young where the red blood cell picture is indicative of pernicious anemia, but where the clinical course is not characteristic. To decide about the name of this group of cases seems of less importance than clearly to recognize their existence.

In presenting the following two cases attempts have been made to give due consideration to the previous discussion. One patient is alive and making progress; the other is not alive, but autopsy was not obtained.

Case 1.—A young girl, aged 15, was first seen in consultation with Dr. Widen at the Norwegian Deaconess Hospital in Minneapolis.

Present Complaint: Weakness and general malaise of two years' duration; nausea and vomiting for six weeks.

Present Illness: Before the age of ten, she had smallpox and measles, both evidently rather mild. At eleven she started to menstruate, and has been regular ever since, even when her anemia was most profound. When thirteen years of age, she noticed that she tired easily and felt weak most of the time. That summer she was sent to a farm, where she improved to the extent that when the school year started in September, she was able to enter. About Christmas time her symptoms of weakness and general malaise gradually increased until Easter, 1928, when she fainted while walking to church. About this time a definite change in her complexion was noticed. This was described as very pale. In spite of the increase of her symptoms she continued her school work and finished the spring term. That summer, at the age of fourteen, she again went to the farm, but this time there was no improvement. In September she started school again, but at the end of one week she had to stop because of marked increase of general malaise, dizziness, nausea, vomiting and fever. She was put to bed. With rest in bed she improved to the extent that she was able to be up and around. This continued for about two months, and then she took a progressively downhill course with the above symptoms markedly increased. She entered the Norwegian Deaconess Hospital January 19, 1929. No definite diagnosis was made although tuberculosis was considered. After a week in the hospital it was necessary to start feeding her by rectum because of increased nausea and vomiting.

Family history cannot be obtained.

Physical Examination: January 31, 1929: A rather well developed, well nourished, young female, lying comfortably in bed, appearing much older than her actual age. Her hair is prematurely gray. There is a slight icterus of skin and conjunctiva. Eyes react nor-

mally to light and accommodation. Ophthalmoscopic examination shows a few old hemorrhagic spots in both retinæ. The discs are very pale, otherwise normal. The tongue is clean, smooth on the edges and atrophic, no soreness present. Tonsils have been removed. Teeth and gums are in good condition. Mucous membranes very pale. Neck shows nothing abnormal. The stage of nutrition is remarkably good considering the duration of the illness. The lungs are normal, presenting a slightly exaggerated type of vesicular breathing. The heart is normal in size and position. There is a systolic murmur heard at the apex. Blood pressure 112/90. The abdomen is normal except for the spleen, which is just palpable at the costal margin. Rectal examination reveals nothing abnormal from the pelvic organs. The temperature while in the hospital varied from 36.6° to 39.8° centigrade.

Neurological Examination: Reflexes are all sluggish. The position sense of the big toe is questionable. Babinski is negative. The patient states that her toes are numb, but objective examination is negative.

Summary of Laboratory Examinations: Blood (January 31, 1929)—Hemoglobin 15 per cent (Sahli), red blood cells 800,000, white blood cells 2,000. Blood smear showed numerous pernicious anemia neutrophils with many myelocytes and premyelocytes, occasional myeloblasts, normoblasts, and megaloblasts, young and atypical monocytes and many degenerating small lymphocytes. The detailed blood study by Professor Hal Downey is as follows:

2/5/29—On this date the blood picture was the most typical of pernicious anemia. Pernicious anemia neutrophils very numerous, but there are not many of the "toxic" type. Myelocytes and premyelocytes very numerous, and there is an occasional myeloblast. Normoblasts and megaloblasts. Young and atypical monocytes and many degenerating small lymphocytes.

2/7/29—Slight polychromatophilia of reds. Normoblasts, but no megaloblasts. Premyelocytes, myelocytes and metamyelocytes are very numerous. Toxic and pernicious anemia type of neutrophil. Young and atypical monocytes.

2/13/29—Marked polychromatophilia. Some myelocytes and metamyelocytes. A few normoblasts. Not very many pernicious anemia neutrophils. Some polymorphonuclears of toxic type.

2/21/29—Last date when smears were made. Anisocytosis, macrocytes and microcytes. No polychromatophilia. No nucleated reds. No myelocytes and only a few typical pernicious anemia neutrophils. There are still a few atypical monocytes and an occasional degenerating small lymphocyte.

In all the above examinations the blood smear showed all stages of hyperchromasia and anisocytosis of reds.

Blood Wassermann negative. Widal negative. Agglutination test for bacillus melitensis negative. Blood urea nitrogen 14 mg. per 100 c.c. blood. Blood sugar 122 mg. per 100 c.c. blood. Icterus index 12, falling to 4 as the patient improved. Gastric secretion after .5 mg. histamine shows a total chloride concentration of 182 mg. per cent, but no free hydrochloric acid and a total acidity of 8. Stool examination revealed nothing abnormal. Urine: Specific gravity varied from 1.014 to 1.022, acid, negative for albumin and sugar. Microscopic examination showed occasional epithelial cells, otherwise negative.

Diagnosis: Pernicious anemia.

Treatment: Because of the patient's critical condition, a blood transfusion was considered, but deferred since previous experience with other cases had given us the impression that the effect of liver therapy is less marked after blood transfusion. The patient was grouped and donor arranged for so that, if necessary, a transfusion could be given without delay. Although the patient was nauseated and vomited, she was given 32 capsules of Stearn's liver extract the first day. She vomited the second dose, but it was repeated. The following day she was given 29 capsules, and she was able to retain them all. She was given 30 capsules daily for the next eleven days, 25 capsules daily for the next six days, 15 capsules daily for the next seven days, then 10 capsules daily for the remaining days in the hospital and was discharged on 6 capsules daily. Seven of Stearn's capsules corresponded to 112 grams of liver. The patient was also given dilute hydrochloric acid with her meals. This was not started at once, but when it was started the patient noted a marked improvement in her appetite. She was given a high vitamin, high caloric diet.

Clinical Course: At first it was hard for the patient to take the capsules, but as the doses she vomited were repeated she soon stopped vomiting. At the end of the third day there was a marked clinical improvement as well as a laboratory response in the form of a reticulocyte increase (Chart 1). After one week there was a definite increase in both the red blood cells and in the hemoglobin and a marked response in the reticulocytes. The patient could start to use a back rest one week after liver therapy was instituted. At the end of three weeks she was up in a wheel chair, taking a few steps at the end of twenty-eight days. She was discharged February 28, 1929, with a hemoglobin of 68 per cent and 3,750,000 red blood cells and was able to walk out of the hospital. She has, up to September, 1929, gained 40 pounds in weight and her face is ruddy and it is not necessary for her to use rouge. In spite of this it has not been possible to bring her hemoglobin above 71 per cent nor her red blood cells above 4,200,000. Up to this time she has received raw liver, Lilly's Liver Extract No. 343, cod-liver oil and iron, and bone marrow and iron, without any further increase in her hemoglobin.

On May 15, 1929, the patient returned to the clinic, complaining of numbness of her feet. As she walks in her home she has a tendency to stumble over the rugs. A complete neurological examination at that time failed to reveal any objective signs of a cord lesion.

The patient was admitted to the University Hospital November 15, 1929, with a hemoglobin value of 22 per cent and a red blood cell count of 1,100,000. The patient during the last two months has admittedly been

careless about keeping up her diet. She has been taking only 4 capsules of Stearn's Liver Extract two or three times a week. From September, 1929, to November 11, 1929, the patient was not under our observation. She states that soon after she began neglecting her diet her weakness and diarrhea gradually returned until the last week in October it was necessary for her to go to bed. She entered the University Hospital with

Case 2.—A. N., a white female aged 18, was admitted to the University Hospital July 9, 1925, and discharged October 28, 1925.

During childhood the patient enjoyed good health. She had no infectious disease except measles at six years of age and was not sick again until April, 1925, when she ate some canned beef. She was in bed at that time for a few days. About the first of May she

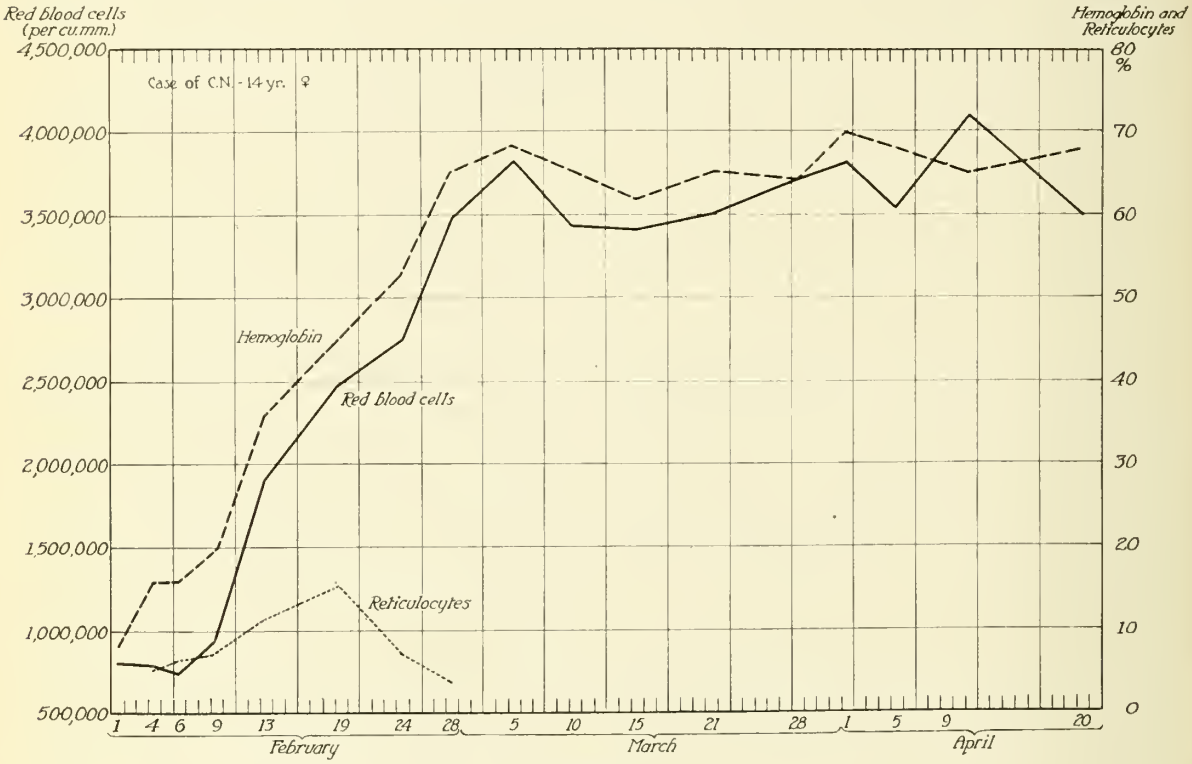

Chart 1

chills and fever caused by an acute sinusitis. The white cell response to this infection was very marked. There was a marked shift to the left with myeloblasts, leukoblasts, promyelocytes and myelocytes. The total white count at the height of her infection was 9,950. Fourteen days later the blood showed a remarkable improvement to the extent that only an occasional myelocyte and pernicious anemia neutrophil was present. There was still anisocytosis and poikilocytosis present. While in the hospital she was given large doses of Lilly's Liver Extract and at the end of three weeks we were able to discharge her with a hemoglobin of 60 per cent and a red blood count of 3,100,000, and she was to receive 6 vials of Lilly's Liver Extract daily for the first week after discharge, and 4 vials daily thereafter. The patient made a remarkable clinical improvement on this short stay in the hospital. The objective neurologic examination on this admission was still negative.*

*Recently this patient has been given linseed oil, 2 tsp. T.I.D., and her liver dosage reduced to 2 vials of Lilly's daily. On this régime the hemoglobin increased to 72% and the red count reached 5,380,000.

noticed that she became fatigued very easily and that she would get more dyspneic when walking fast. It was difficult to keep her hands and feet warm. This continued until one week before entrance into the hospital, when she noticed numbness and tingling in her fingers and toes. She found it necessary to spend most of her spare time resting. About the tenth of May her friends began to tell her that she was getting very pale, but she continued her high school work until May 18, when she stopped because of weakness and went to bed. She stayed in bed until June 8, when she was able to be up and around, but did not have the strength to carry on her usual work. During this illness there were times when her tongue was sore and occasionally she had attacks of epistaxis. Her menstrual history was essentially negative. The family history was negative except for the death of one brother at the age of nine from brain fever.

Physical Examination: Girl, very anemic in appearance, lying quietly in bed apparently in no discomfort. She appears much older than her actual age. She is well developed and well nourished; weight 48 kg. Skin shows a slight icterus. The face appears some-

what swollen, but there is no pitting on pressure. Pupils normal, sclera is bluish-white, conjunctivæ very pale. Mucous membrane of the mouth very pale. Teeth in good condition. Tongue shows an atrophy more noticeable on the borders of the tongue. Tonsils and pharynx show no abnormality. Neck within normal limits. Chest—patient complains of nightly pain over the sternum. This at times is exaggerated by palpation. Lungs show no abnormalities. Heart normal except for a soft systolic murmur at the apex and an accentuation of the second pulmonic sound. Blood pressure 110/50. Abdomen—spleen palpable under the costal margin; otherwise no abnormal findings.

Neurological Examination: The patient gave a typical history of paresthesia of hands and feet, but the Neurological Service was unable to demonstrate any signs of combined degeneration.

Laboratory Examination: Temperature varied from 37° to 38.5° centigrade, and pulse from 80 to 120. Blood examination on admission—20 per cent hemoglobin, 1,080,000 red blood cells, 4,300 leukocytes. Differential count—24 per cent polymorphonuclears, 70 per cent lymphocytes, 4 per cent large monocytes and 2 per cent eosinophils. Detailed blood study by Professor Downey showed numerous pernicious anemia neutrophils with megaloblasts and normoblasts with marked macrocytosis and some poikilocytosis. The blood did not improve morphologically while in the hospital, but there was some improvement up to 35 per cent hemoglobin and 1,520,000 red blood cells. The direct van den Bergh test was negative; the indirect positive and quantitated to 35 units. Examination of the gastric function (Ewald meal) showed an achlorhydria. Wassermann was negative. Blood chemistry normal. Basal metabolic rate within normal limits. Fragility test—hemolysis began at .38 per cent sodium chloride and was complete at .34 per cent. Numerous examinations of the feces revealed nothing abnormal. Parasites or ova were not found. Repeated urine examinations did not reveal any presence of albumin or sugar.

DISCUSSION

Two cases of what might well be diagnosed as pernicious anemia in two girls aged 15 and 18 years have been reported. In the first case the blood morphology was studied in considerable detail by Dr. Madeleine Fallon of this department. Both cases were studied by Professor Hal Downey, particularly the younger and more recent case. The appearance and reaction of the red cells were fully characteristic in both cases. The "pernicious anemia neutrophils" so highly valued as a diagnosticum by the morphologists, but accepted with a certain hesitancy by the clinician, were present in both cases. The reaction of the neutrophils towards immaturity was of special interest in the younger patient. Though it has long been recognized that particularly during a blood crisis immature neutrophils as far back as myeloblasts appear in the circulation in pernicious anemia, this reaction was unusually dominant during the acute septic infection which prevailed at the second admission of the younger patient. This extensive release of immature forms appears as a rather characteristic bone marrow response in the young.

Clinically striking features in the younger patient are not only her early gray hair, but also her generally early development with a body frame and a development of fat on breasts and hips which usually is not present until fifteen to twenty-five years later.

Achlorhydria was present in both patients.

Subjective neurological symptoms were recorded in both patients, but in both objective neurological signs were missing.

In the older patient no remission ever occurred. In the younger patient one might possibly talk about a remission two summers before the patient came under medical observation. Without liver therapy the end would not have been far off when the patient was first seen. Also it deserves notice that the last relapse came on soon after the first hospitalization and developed rapidly.

It is a point of regret that information as to heredity could not be obtained in either case.

CONGENITAL SYPHILIS*

Ralph R. Sullivan, M.D.
Duluth, Minnesota

TO the laity, congenital syphilis presents a gruesome picture of horrible deformities, of innocent, unfortunate, yet loathsome things; to the medical profession it presents just another problem in diagnosis and treatment. But truly those afflicted are victims of circumstance, whose chances for normal lives are too often viewed with unpardonable pessimism, never with undue optimism. Congenital syphilis presents itself as a problem to society as a whole, but more particularly and more definitely to the obstetrician, the pediatrician, the internist, the syphilologist and the general practitioner, not to mention the specialist in eye, ear, nose and throat. In brief, upon all of them depend the ultimate decline in the incidence of the disease and the satisfactory treatment and relief of those afflicted with it.

There is ample evidence in the literature to prove that the incidence of congenital syphilis is great enough to insure it an important place, indeed, among the medical problems of today. Minimum figures given by Stokes place the incidence of syphilis in the child population as a whole as ranging from 3 to 5 per cent.[5] Jeans and Veeder of St. Louis in their own hospital material found 2 per cent among 5,185 new patients—with an incidence of 4.9 per cent in those under one year—latent cases not included.[4] The Wassermann has shown that many cases without any clinical evidence of syphilis have a latent infection, Wirz having shown that as high as 3 per cent of apparently non-syphilitic babies have a positive Wassermann reaction. Quoting Jeans and Veeder: "It is useless to estimate the number of syphilitic children. We know that there are many more than we estimated a few years ago."

My purpose within the scope of this short paper is to present a series of cases as observed and treated at St. Mary's Hospital, over a period of ten years, and to compare such a study with those reported by some of the larger clinics; but before doing that I should like to summarize briefly some rather interesting points from the literature. 1. The prognosis in congenital syphilis is generally good as evidenced by statements by leading pediatricians and syphilologists of the country. From Jeans and Veeder comes the encouraging statement: "As well as can be judged in the period since the use of the newer remedies and the more recent method of application, infants who are well treated do not later have any manifestations whatever of syphilis and enjoy as good health as though they never had the disease."

2. The best treatment of the infection is prophylactic, which brings us to the great responsibility which rests upon every doctor who cares for the expectant mother. Out of 1,332 pregnancies in 250 syphilitic families reported in the literature, 22.7 per cent ended in miscarriages and stillbirths, 20.8 per cent in infant deaths, 58 per cent in living syphilitic children and 18.3 per cent living healthy children; among 1,366 living births in syphilitic families 30 per cent died in infancy.[4] In all, it represents a tremendous toll upon human life—especially significant when it is stated that antiluetic treatment of the mother during her pregnancy will result in non-syphilitic offspring—though this treatment is not by any means sufficient to produce a cure.

3. No matter how late the expectant mother comes to the doctor, it is worth while treating her even though the fetus is already infected. The treatment should not be too intensive and should be governed by the period of gestation and stage of the infection. It should be modern treatment and should include the use of the arsphenamines particularly, with bismuth and mercury as valuable adjuncts. Stokes' outline of treatment in Modern Clinical Syphilology is perhaps the best available for reference and should be consulted.

4. Careful histories and routine use of the Wassermann will save many mistakes and go a long way in the battle against congenital syphilis.

5. It is generally conceded by most authorities that infection of the child takes place through the maternal blood stream and placenta —and that the treponema can be recovered from the same.

*Presented at a meeting of the Staff of St. Mary's Hospital, at Duluth, Minnesota Dec. 5, 1929.

6. The child is probably infected after the third month in most cases, though it may be infected at any time during intrauterine period. The date of the infection, its virulence and extent of the mother's defense mechanism may determine whether the infection after birth will be a far advanced, infantile or tardive form.

There are, briefly, three types of congenital syphilis: (1) fetal and syphilis of the newborn; (2) infantile or early congenital syphilis; (3). late or tardive congenital syphilis.

The first type is the one which results in death in the embryonal stage, in the fetal stage, at birth, or shortly after—a few hours to a day or two. The diagnosis is made on the appearance of the placenta but best upon the basis of finding the spirochetes in the organs of the fetus. Pathologic examination of the placenta and study of the fetus by a pathologist is recommended in every case, along with family investigation and maternal and fetal Wassermanns. Careful investigations and study will lead to the diagnosis and treatment of the mother and the protection of all subsequent pregnancies. Therefore, it is, from the standpoint of preventive medicine, the most important type to recognize.

The second type, or infantile congenital syphilis, represents a very interesting but frequently very discouraging picture of the infection. The blood Wassermann, which is negative in 37 per cent, weakly positive in 18 per cent, and strongly positive in only 45 per cent, according to Stokes, cannot be relied upon absolutely for the diagnosis. Certain authors do maintain, however, that all syphilitic infants have strongly positive Wassermanns after the first few weeks or months of life. In the small series of ten cases observed here, 80 per cent were strongly positive. The stigmata were fairly marked in 80 per cent of the cases and entirely absent in 20 per cent; but in the latter the Wassermann reaction was positive. The following table taken from Stokes[5] summarizes fairly well the chief symptoms to be kept in mind at all times when observing the infant:

SUMMARY OF CHIEF SYMPTOMS OF INFANTILE CONGENITAL SYPHILIS

Eruption—Rare before third week, distribution distinctively to face and mouth region, the anogenital region, and palms and soles; macular, maculopapular, secondarily eczematous and often infected. Condylomas and mucous lesions. Pemphigoid bullæ, 10 per cent.

Snuffles—As common as eruption and as early. May be mild and not distinctive; almost diagnostic if hemorrhagic.

Hacking of Lips—Fissures, especially of the upper lip and middle of the lower.

Rhagades—Infiltrative, fissures, eczematous involvement of cheeks, and chin near the commissures.

Enlarged Spleen—Almost diagnostic before the fourth month.

The Cry—Cracked and aphonic. Very suggestive.

Pseudoparalysis—Flaccid of upper extremity, spastic of lower, presumably due to painful movement, but may be neuritic; due to osteochondritis and epiphysitis.

Osteochondritis, Chondro-epiphysitis, and osteomyelitis—Palpable enlargement and tenderness of ends of long bones, single or multiple; most often there may be a fusiform involvement of shaft of the bones in the upper extremities.

Saddle Deformity of Nose—The sequel of the osteitis and gummatous changes in snuffles.

Pulmonary, Hepatic, Marasmic Symptoms—Less common.

The series in the venereal clinic here is so small that any conclusions are unreliable, but I have included in the next table the admittance signs and symptoms as they were casually observed. More detailed examinations at the time, in all probability, would have revealed many more.

10 Cases of Infantile or Early Congenital Syphilis

1. Snuffles, 6.
2. Hydrocephalus, 2.
3. Hacking of Lips, 1.
4. Paronychia, 1.
5. Osteochondritis, 1.
6. Rhagades, 1.
7. Papular Lesions (Syphilides), 2.
8. Chancre on Tongue, 1.
9. No stigmata at all, 2.
10. Positive Blood Wassermann (first), 8.

The third type, the late or tardive syphilis, comprises the majority of the cases of congenital syphilis seen in this clinic, and is the most interesting of all congenital syphilis because of the diversity of its manifold signs and symptoms.

Again, because of lack of time, I am confining myself to a summary and comparative study of the incidence of these signs and symptoms in our series and that of Jeans and Veeder of St. Louis, with a comparison also of the most common signs and symptoms in a series of 202 cases reported by Stokes. I am sure that more of the conditions listed by this author would have been covered in the cases here if a careful study had been made with aid of the *x*-ray and spinal fluid analysis.

The reader will note the striking incidence of the eye lesions, particularly the interstitial keratitis, which in turn indicates the important part

which the doctor plays who specializes in eye, ear, nose and throat. In this connection it might be mentioned that the anti-syphilitic treatment in the presence of an interstitial keratitis should always be done with the coöperation of an ophthalmologist if possible. I was interested to note in an account by Ehlers[3] on the fight against congenital syphilis in Scandinavian countries that the incidence of interstitial keratitis was given as 60 per cent; and that the complete Hutchinson triad was observed in only two cases during the author's sixteen years of observation.

Now we pass over to consider for a moment the treatment employed in congenital syphilis; and summarizing the treatment, including that employed by Stokes, Jeans, and Veeder, and of Dickey and Sutton of California, the following conclusions may be drawn:

1. The arsphenamines, either arsphenamine or neoarsphenamine, are to be preferred. They are best given intravenously when that method of administration is practicable.

   (a). The dose of arsphenamine employed is .025 at two weeks to 0.1 gm. from six weeks to two months. The dosage in older children is based on the child adult ratio, according to the case. (Jeans employed .01 gm. per Kg. body weight.)

   (b). Neoarsphenamine, which may be used intramuscularly, is given in doses of 0.2-0.3 gm. by Stokes in the one to two year period. (Jeans used .015 gm. per Kg. body weight.)

   (c). Sulpharsphenamine is used by Sutton and Dickey because it can be given intramuscularly without irritation. Dose .015 gm. per Kg. body—increasing to .03 during first eight injections.

In the clinic here the sulpharsephenamine was used intramuscularly in doses of .015 to .03 gm. per Kg. body weight, until the child became old enough to make intravenous therapy practicable. Then neoarsphenamine in amounts bordering on adult doses .1 to .4 gm. was used in practically all cases.

Intravenous administration was conveniently employed at four years in a number of cases coming in at that age. Neoarsphenamine was not used intramuscularly because of the marked irritation which results in many cases.

2. Bismuth in the form of bismuth phenylformitate in doses of 15 mg. per Kg. body weight is used in preference to mercury by Sutton and Dickey.[2] Bismuth in form of Bismogenol is preferred over mercury also by Dr. H. E. Michelson at the University of Minnesota.[6] Bronson at the New Haven Dispensary used potassium bismuth tartrate in dose of 0.1 gm. regardless of age.[1] This author, in a series of thirty-one cases treated, stresses the value of bismuth in children because: (1) it is well tolerated; (2) it can be used effectively in those cases intolerant to arsenic; (3) it proved particularly favorable in the cases of interstitial keratitis and syphilis of the central nervous system, treated.

The experience of the St. Mary's Hospital clinic with both bismuth potassium tartrate and the salicylate in dosage of 0.1 gm. has been very satisfactory.

3. Mercury in the form of the bichloride in doses of approximately 5 mg. per Kg. body weight for infants (Sutton and Dickey) or .03 c.c. of a 1 per cent solution per kilo. of body weight (Jeans), is used by a number of writers. Mercury rubs, in the form of the official Unguentum Hydrargyri .05 gm., is still advocated, but particularly in infants. Stokes uses the rubs in doses of 1 gm. in young infants to 4 gms. in older children once daily. Jeans likes to use metallic mercury in finely divided chalk in dosage of 1/5 gr. t.i.d. for young infants to 2 gr. or more t.i.d. for larger children; but most of the other writers do not. Mercury succinimide in doses of 1/20-1/4 gr. is used more than any other form in this clinic and seems particularly well tolerated, convenient and effective in the younger children.

4. Potassium iodide in doses of 3-7.5 grains t.i.d. by mouth is advocated in cases of painful periostitis, but is not advised routinely.

5. The basic routine was alike in most respects, and provided for weekly injections of one of the arsphenamines for six to eight doses in a series, a short rest with or without mercury rubs at home, and ten to twelve injections of bismuth or mercury to a series. Intensive, persistent treatment, bordering on adult ratios, was the tendency here, at the University, and with Stokes.

The extent of the treatment is variable; but practically all agree that thorough treatment is byword in congenital syphilis. If active signs of

the infection are present intensive treatment is indicated until such signs disappear and the Wassermann reaction is negative (if latter is possible) At best this will probably mean two years, and frequently longer in the late cases. After this the patient should receive at least moderate treatment over as long a period as possible. By moderate one should include a minimum of two courses a year of bismuth or bismuth and mercury alternately with an occasional series of neoarsphenamine. Dr. H. E. Michelson believes that a congenital luetic should be treated for at least five years and kept under careful observation as long as possible. The policy in our clinic has been to give intensive persistent treatment as long as possible, with the clinical results used largely as the criterion, and the Wassermann reversal as a desirable end-result. Whenever possible, the cases are followed through puberty, the treatment being increased rather than decreased throughout adolescence.

Spinal fluid analysis is advocated by Jeans if no results are obtained from the treatment in six months to a year. Intraspinal therapy (technic similar to Swift-Ellis) may be used in selected cases of cerebrospinal syphilis.

The final basis for discharge in most clinics is a negative spinal fluid and a careful neurological examination. Spinal fluid analysis has not been required in most of the cases in our clinic because they are carried through to maturity under treatment anyway.

In discussing the results obtained generally in the treatment of congenital syphilis, one must admit that they in the main are encouraging. Stokes reports results more favorable than most others, in the following: 82 per cent of 170 cases achieved a good clinical result and 62 per cent a serologic reversal to negative. White and Veeder of St. Louis after evaluating their results over a period of many years give the following: from a total of 208 cases 22 per cent cured or recovered, 35 per cent improved, 17 per cent unimproved and 25 per cent died. In Denmark, where the congenital syphilitic children are received in special asylums, Ehlers reports the ultimate fate of the first hundred children discharged, as follows: 22 per cent died, 37 per cent developed like normal individuals, 28 per cent were backward and showed retarded development and 13 per cent became imbeciles. The mortality in these reports is not given in age groups, but it is probably true that a large percentage are the early fulminating cases where infections of the lung play an important part.

Our results here have been highly satisfactory from a clinical standpoint; much less so from a serological standpoint. In the series of sixty cases, a reversal of the Wassermann was obtained in only 20 per cent; but out of twenty negative on admittance, nineteen remained so under intensive treatment, which leaves a total of 50 per cent persistently positive. Some of these cases have been under treatment but a short time and more reversals may be expected in time. In twelve of the cases of persistently positive Wassermann reaction, bismuth has been used extensively over a number of years along with the neoarsphenamine in hope of reversing the test, without results. Two of our cases died, one of tuberculous meningitis and the other was suspected of having tuberculosis but no postmortem was obtain to verify this. Four of the sixty-one cases were just recently placed under treatment and eight were either transferred to private doctors, or left the city—leaving forty-seven. Of this number all but four have achieved a good clinical result. Twelve cases have to date been carried through puberty, are apparently cured, and show no evidence whatever of having ever been afflicted with congenital syphilis. In a personal communication with Dr. H. E. Michelson, I was able to learn that in his experience with congenital syphilis the clinical results have been very satisfactory in the main; and the serological much less so.

As 50 per cent of our cases here have been under treatment for four years or longer and some as long as ten years, I have endeavored to bring before you, as evidence of our success, as many cases as possible. These are not picked cases; in fact several of our best are holding good positions in the city and were afraid to come here despite the assurance that only the illustrious staff of St. Mary's would be present:

Case 1.—L. W. is a female baby now one year of age who was brought to the clinic at two months of age with florid rickets, large head, marked snuffles, fissures of hands, feet and mouth; and was then scrawny and appeared quite toxic. The Wassermann reaction was Kolmer positive. Because of the marked activity of the syphilis, the baby was given twenty mercury rubs followed by a rest of three months. Since then it has been on sulpharsphenamine intramuscularly. As you see it now the snuffles have completely cleared up, there

has been a marked gain in weight and sufficient body development to offset the previously large head. Its teeth are erupting normally and the rickets is apparently controlled.

Case 2.—F. S. is a twelve year old girl, who was admitted to the clinic without previous treatment one year ago with a marked bilateral interstitial keratitis. She was markedly underdeveloped and undernourished; but apparently was not retarded mentally. There was considerable scarring from previous fissures about the nose, mouth, anus and vagina. The Wassermann was Kolmer positive. Her treatment has consisted of mercury succinimide largely, with neoarsphenamine intravenously. As you see her now there has been a marked gain in weight and some developmental improvement. The keratitis has receded and the child seems quite well. We hope to prevent a recurrence and will give the patient the benefit of continued treatment, including bismuth.

Case 3.—B. K., a female, aged 5, was admitted to the clinic at the age of 3 months with marked snuffles, hydrocephalus, and in a state of undernourishment. The Wassermann reaction was Kolmer positive, and has remained persistently positive in spite of the following treatment:

Course 1.—24 mercury succinimide (.05-.10 gr.)—1 month rest.
Course 2.— 6 neoarsphenamine and 24 mercury succinimide—1 month rest.
Course 3.— 6 sulpharsphenamine and 24 mercury succinimide—1 month rest.
Course 4.—12 sulpharsphenamine and 24 mercury succinimide—1 month rest.
Course 5.—12 sulpharsphenamine and 15 bismuth potassium tartrate (.1 gm.).

As you see her now, the large head is not noticeable because the body development has literally "caught up" to the head. The child walked and talked at the normal age; her teeth developed and she seems quite bright mentally.

Case 4.—O. C., a young woman nineteen years of age, was admitted to the clinic five years ago because she had definite Hutchinson teeth, and was thin, underdeveloped and anemic. The Wassermann was Kolmer positive. The patient had not had any previous treatment. Her progress in school was not good though she was not subnormal. The treatment was instituted as follows:

Course 1.— 6 neoarsphenamine (.3 gm.), 24 mercury succinimide (.1 gr.)—3 mo. rest.
Course 2.— 6 neoarsphenamine (.4 Gm.), 24 mercury succinimide (.2 gr.)—1 mo. rest.
Course 3.— 6 neoarsphenamine (.4 gm.), 24 mercury succinimide (.2 gr.)—1 mo. rest.
Course 4.— 6 neoarsphenamine, 15 bismuth potassium tartrate—2 mo. rest.
Course 5.— 9 neoarsphenamine, 24 mercury succinimide—2 mo. rest.
Course 6.—15 bismuth—4 mo. rest.
Course 7.— 6 neoarsphenamine, 15 bismuth.

The Wassermann has remained persistently positive. There is nothing to indicate now as you look at this —you will admit—very good looking young lady, that she ever had been afflicted. She has developed perfectly through puberty, seems bright and quite normal in every respect.

Case 5.—B. C. is a sister of the patient just observed, is now twenty-one years of age, and was referred by a private physician five years ago. She had been under the care of a doctor three years before for poor vision, but received no anti-syphilitic treatment. She was placed in the sight-saving class at school. At the time she appeared at the clinic she was markedly undernourished and underdeveloped. Her vision was 20/200 in both eyes due to interstitial keratitis of a chronic type. The Wassermann reaction was Kolmer negative on admission, became positive after the second course of treatment and has been negative repeatedly since. Treatment was started immediately as follows:

Course 1.— 6 neoarsphenamine and 24 mercury succinimide (.2 gr.)—1½ mo. rest.
Course 2.—15 bismuth—1 mo. rest.
Course 3.— 9 neoarphenamine and 24 mercury succinimide—2 mo. rest.
Course 4.— 6 neoarsphenamine and 15 bismuth—2 mo. rest.
Course 5.—15 bismuth—3 mo. rest.
Course 6.— 9 neoarsphenamine and 24 mercury succinimide—2 mo. rest.
Course 7.—15 bismuth—3 mo. rest.
Course 8.—15 bismuth—2 mo. rest.
Course 9.—15 bismuth and 15 neoarsphenamine.

The patient consented to come tonight and again you see no evidence of any previous trouble. She is well developed, very well nourished and her sight is uniformly good, according to the eye specialist's report. She has married and with her now is her perfectly normal baby.

Case 6.—The next two cases are brothers. The first, twelve and one-half years old, came to the clinic at five and one-half years of age, poorly developed, undernourished, and very backward (was reported as feebleminded at the time). The lens in one eye was loose. The Wassermann reaction was Kolmer negative and has remained so since. His treatment has consisted of four courses of twelve neoarsphenamine and fifteen bismuth injections. Rest periods much longer than usual were given in this case.

His physical condition is excellent as you see; but he is still very retarded mentally.

Case 7.—This is a younger brother of the preceding case, now ten years of age, who was admitted to the clinic six years ago, very small for his age, thin, scrawny, and anemic. His Wassermann reaction was Kolmer negative and has remained so. The child was retarded mentally and had begun to walk and talk very late. He was placed on rather intensive treatment as follows:

Course 1.— 6 neoarsphenamine—2 mo. rest.
Course 2.— 9 neoarsphenamine and 34 mercury succinimide—18 mo. rest.
Course 3.— 9 neoarsphenamine and 34 mercury succinimide—5 mo. rest.

Course 4.— 6 neoarsphenamine and 24 mercury succinimide—6 mo. rest.
Course 5.— 9 bismuth—5 mo. rest.
Course 6.—12 neoarsphenamines and 9 mercury succinimide—6 mo. rest.
Course 7.—12 neoarsphenamines and 15 bismuth.

This boy has developed quite well but not nearly as well as his older brother; yet he is much ahead of him mentally for he is considered very bright in school.

Case 8.—H. M. is a boy, aged 11, admitted to the clinic four years ago with a history of being backward in school. The parents were syphilitic; but the child's Wassermann was Kolmer negative and has never been positive. No previous treatment had been given and the child was markedly underweight and underdeveloped.

The first course of treatment consisted of twenty-four mercury succinimide and six neoarsphenamine injections. Since that he has received four courses, six neosalvarsan and 15 bismuth in each. At present he is getting along very well in school, and is in very good physical condition.

Case 9.—A. M. is the sister of the above case and is ten years old and had been under treatment two years. At the time of her admission she had Hutchinson teeth, was underdeveloped and undernourished, and anemic. The Wassermann reaction was Kolmer negative repeatedly. Her treatment has consisted of four courses of six neoarsphenamine and 12 to 15 bismuth injections each.

Her present state is very much improved physically. Note her teeth, which are in good condition though the Hutchinson characteristics still remain.

Case 10.—H. F. is a boy aged 9, who has a very interesting history. He was seen by a doctor eleven months after birth. At that time he had an enlarged head, rhagades, snuffles, badly decayed teeth, markedly enlarged liver and spleen, discharging ears, and scars on the buttocks. The Wassermann reaction was Kolmer positive. The baby had been given some mercury rubs by some doctor before this (amount not known). Treatment at that time consisted of eleven injections of $HgCl_2$ (3 mg.) and mercury rubs at home. He was also given two small neoarsphenamine injections (.1 and .15).

This patient was not seen again until he was seven years old, at which time he had a paralysis of the entire right side of the body, the right eye being turned inward markedly. The Wassermann taken at that time was positive. He was given protiodide of mercury for a while without any change and was apparently lost track of.

He was brought to the clinic a short while ago when it was noted that he limped markedly on walking and was unable to hold a lead pencil in his hand. The eye was still turned in somewhat. Since then he has received nine injections of neoarsphenamine and eight mercury succinimide. The child's arm has improved and he is able to hold objects without any trouble. As evidence let this little fellow grip your hand.

Case 11.—R. L. is a boy about five and a half years old, who was brought to the clinic when four months old with snuffles, fissures, rickets and a weak, wailing cry. He was undernourished and very apathetic. The Wassermann was Kolmer positive. His treatment was as follows:

Course 1.—20 mercury succinimide (.05 gm.), 6 neoarsphenamine (.1 Gm.)—1 mo. rest.
Course 2.—12 sulpharsphenamine (.2 gm.)—2 mo. rest.
Course 3.— 9 sulpharsphenamine and 20 mercury succinimide—5 mo. rest.
Course 4.—20 bismuth—3 mo. rest.
Course 5.—15 bismuth—3 mo. rest.

There was marked improvement in his condition; he talked and walked normally. He has not received any treatment for a year because of his exceptionally good physical and mental condition and the repeatedly negative Wassermann.

Case 12.—F. B. is a very interesting case because it represents one of those unfortunate cases of late congenital syphilis. This young man, now eighteen years old, came under the clinic's care three years ago, at which time he was bedridden and in terrible shape. He was actually an emaciated, haggard dwarf, with a perforated palate and septum and extensive necrosis of the nasal bones. Instead of talking he had to whisper. His mental retardation was marked. Just when the stigmata first appeared is not known exactly; but we have snapshots of the patient as a baby and at about thirteen years of age (pictures passed around). In both he appears perfectly normal; and at thirteen years he was apparently a larger fellow than he is now.

The Wassermann reaction was Kolmer positive, became negative after the fourth course of treatment and has remained so. His treatment was as follows:

Course 1.—24 mercury succinimide and 12 neoarsphenamine—1½ mo. rest.
Course 2.—15 bismuth K. tartrate and 9 neoarsphenamine—2 mo. rest.
Course 3.—15 bismuth K. tartrate and neoarsphenamine—1½ mo. rest.
Course 4.—15 bismuth tartrate and 6 neoarsphenamine —4 mo. rest.
Course 5.—12 neoarsphenamine. Put on rest with potassium iodide.

Before the first course was completed the patient was able to get out of bed and was brought to the hospital for operation on his nose. As treatment was continued he began to get about on crutches, gained weight and was able to talk at least, though with a gruff, cracked voice. For the past year he has been able to run around, and has taken over the burden of supporting the family by starting a chicken farm. We feel particularly proud of this case because it represents the return of an invalid, a public charge, to a useful, responsible place in society. Unfortunately, this fellow is going to carry these stigmata through life; and a Wassermann in childhood would have saved this.

CONCLUSIONS

1. Congenital syphilis is more prevalent than is generally believed and is a definite medical problem.

2. The prognosis is generally good, as evidenced by leading authorities throughout the country.

3. The best treatment is prophylactic—which means routine Wassermann tests on all pregnant women and immediate, adequate treatment if positive, regardless of the stage of gestation.

4. Good histories, maternal Wassermanns and also blood tests of the infant in questionable cases will go a long way in the battle against congenital syphilis by assuring an early diagnosis. Do not rely upon the absence of stigmata in ruling it out.

5. Intensive, persistent, modern treatment bordering on adult doses (unless condition contraindicated this) and careful observation through puberty should be the by-word in congenital syphilis. This should include the arsenobenzols, and either bismuth or mercury, or both, in adequate doses.

6. The comparative study reveals a uniform similarity between the larger clinics and the one here, in admittance signs and symptoms and treatment. The results differ somewhat.

7. The cases presented give you a practical demonstration of what can be done with congenital syphilis.

A PLEA FOR THE RADICAL TREATMENT OF INCOMPLETE ABORTION*

Albert G. Schulze, M.D.
Saint Paul

PRESENT day medical literature devotes much space to the subject of abortion, its etiology and classification, but more particularly and with more emphasis to the question of its treatment.

There is very little, if any, notable difference of opinion concerning the treatment of threatened and inevitable abortions, but one might venture the statement, without much fear of contradiction, that there are two very distinct schools of opinion when the question of treatment of the incomplete type of abortion is under discussion. These might be called the conservative and the radical schools.

Neither method seems to be followed to the absolute exclusion of the other but most authors follow conservative methods for longer or shorter periods of time and then, when confronted by defeat, adopt the more radical treatment.

During the last five years I have had an excellent opportunity in my service at the Ancker Hospital to see an unusually large number of abortion cases of the incomplete type. At first and early in this work I adopted the curette as my method of treatment with a feeling of fear rather than with a desire to be conservative. I was soon impressed, however, with the remarkable cessation of uterine bleeding and cramps and the rapid convalescence which an instrumental curettage afforded my patients.

These excellent results prompted me to adopt this as the routine method of treatment, safeguarded by a few restrictions, and it is my purpose in presenting this thesis to give a clinical and statistical review of 235 cases of incomplete abortion which I personally curetted, and to note if the facts as revealed by such a survey harmonize in any degree with the mental impression that was gained while the work was being done; also to give my reasons for adopting the radical treatment.

The technic which I adopted was as follows: As soon as practical after admittance to the hospital, the patient is prepared localy and all blood clots and masses passed from the vagina are kept for inspection.

When the patient is under the anesthetic ready for the operation a second bimanual examination is made and she is given a hypodermic of 1 c.c. of pituitrin. The vagina is cleansed with alcohol, the cervix is steadied with a tenaculum and brought forward, care being taken not to make too much traction, and the os is dilated with a Goodell dilator if need be. Gentleness is exercised in inserting the curette into the uterus to avoid the possibility of perforating the organ. The tenaculum is always held by the operator; never by the assistant.

When the uterus is emptied of the remnants of the products of conception its interior is dried by inserting a packing of plain gauze. This is removed and another strip, soaked in 3 per cent iodine, is inserted. This is removed after a moment and a third strip is inserted. This last packing is removed after 24 hours and the patient is given a dram of the fluid extract of ergot, which medication is repeated after six hours.

The purpose of allowing a packing to remain *in situ* for 24 hours is to stimulate the uterus to contract, protect the patient against any possible bleeding and to facilitate the separation of any small remnants which might have been overlooked. The value of this may be over-estimated.

This method of treatment very likely would be endorsed by some authors; regarded perhaps as unnecessarily radical and hasty by others; and most severely criticised by a third group.

Gordon states that curettage often changes an aseptic case to a septic one and is seldom indicated and often harmful.

Child believes that the curette has no place in the treatment of abortion and condemns it severely, while Tovey thinks that the uterus

*Thesis presented before the Minnesota Academy of Medicine, Saint Paul, Feb. 19, 1930.

should never be curetted. Yates thinks that the curette has killed more persons that it has saved.

Gordon resorts frequently to light vaginal packing which he is obliged to repeat in 20 per cent of his cases and is often obliged to do it a third time. He thinks that curettage may be indicated after a second or third packing. He treats conservatively until it fails and he admits failure in 4 per cent of his cases.

Healey criticises this conservatism, regards packing as not being without its danger, and that it often fails to loosen the product of conception and he favors a curettage as he thinks that there are fewer later complications. Aranow favors a curettage.

Hillis, even in the presence of a temperature, does not pack but empties the uterus with the least possible trauma and thinks that in his series of 1,000 cases curettage did not lengthen the febrile period. He thinks that expectant treatment in non-septic cases is doomed to failure in 40 per cent of cases.

The most frequent objections voiced against the radical treatment of incomplete abortion are the danger of perforation of the uterus; failure to remove all the remnants of the products of conception; damage to the uterine wall; and the fear of infection. On the other hand, many advocate the use of the index finger as the safer method. Magid uses the finger as soon as the os is open and Yates favors this method. Gellhorn thinks a sharp curette is far less violent than a blunt one and lodges the same criticism against the digital curettage.

Let us consider digital curettage first. Many cases of incomplete abortion that are sufficiently sick to be admitted to a hospital have rather large subinvoluted uteri with deep cavities, and at times the decidual remnants are still firmly attached. In order that the index finger may explore the whole of the uterine cavity and reach as high as the fundus, it is necessary that the operator insert his whole hand in the vagina and make firm pressure on the uterus in order to telescope it over the exploring finger. The finger must be of more than average length and one encounters the added difficulty of having the os plugged by the larger proximal end of the finger.

This is a dangerous procedure. When one recalls Sampson's work on the etiology of endometrosis and the possibility of the escape of the menstrual blood from the fimbriated ends of the tubes under the pressure of rather mild uterine contractions, it is easy to comprehend how it is very possible and highly probable while doing a digital curettage to force some of the uterine blood, mucus and other debris through the tubes and into the abdominal cavity. Furthermore, and as will be shown later in this discussion, this uterine material is often infected although the patient's temperature and the local condition might not suggest it.

Regarding the possibility and danger of a uterine perforation, it is a valuable safeguard to make a second bimanual examination while the patient is under the anesthetic and the administration of 1 c.c. of pituitrin at this time aids the uterus in its involution. While I encountered many retro-uteri with displacement of varying degrees, and many organs with deep cavities and soft doughy walls, it was not my harrowing experience to perforate a single uterus in this series of 235 cases.

It is true that if one were to subject the interior of the uterus to a microscopical examination after an instrumental curettage, no doubt many decidual and chorionic remnants could be found. This is theoretical and not practical. In this series of cases it was my embarrassment on only one occasion to be obliged to curette a patient the second time.

If one may regard the pathologist's reports as any criterion of the subject, one is impressed with the fact that the presence of uterine muscle in any abundance in the curettings is very infrequent; he reports it only once.

While on this subject perhaps I may be permitted to state that in not a single instance did the pathologist's report make mention of the presence of a fetus in the curettings.

The danger of infecting a patient through curetting is not great if one is careful of his technic and gives proper consideration to self-induced abortions and the presence of fever. Gordon regards his patient as septic if she has a rectal temperature above 101 or if the abortion was induced or if there have been subsequent intra-uterine manipulations. Gellhorn regards the treatment of criminal abortion as synonymous with sepsis and regards all septic abortions as criminal and thinks that 90 per cent of them should be so classed.

The point is often emphasized that while a

uterus can withstand the trauma and possible introduction of infection occasioned by a first dilatation of the internal os, it cannot withstand a second such dilatation. This may be true. But I take the stand that when a uterus is subinvoluted and bleeding and harboring foreign material in the form of remnants of the products of conception, which themselves are often undergoing degenerative changes, it is more beneficial to the patient and very safe indeed to dilate the internal os amidst the surroundings of a present day operating room and stimulate and assist this important pelvic organ to return to normal. Furthermore, in many of these cases the internal os is wide open, allowing infection free entrance to the interior of the uterus and it will continue to do so until the uterus is empty.

So, none of the objections so frequently raised against an instrumental curettage of the uterus in incomplete abortion is serious and cannot be avoided. On the other hand, there are some very excellent reasons why such a procedure is very appropriate and holds out many advantages to the patient. In the first place it shortens the patient's stay in the hospital. This shortened hospitalization and reduced expense occasioned thereby are important matters to the average patient and in this series of cases, all of whom were in a municipal institution, it lightens the load of the taxpayers.

These 235 cases spent 1,247 preoperative days in the hospital or an average of 5.3 days each. Sixty-eight patients, or 29 per cent, were in the hospital longer than this average period while 167, or 71 per cent, were in the hospital five days or less, but the largest number only three days. The only conservatism that I displayed here was occasioned by the desire to make a correct diagnosis before resorting to operation and to allow a temperature to return to normal for a safe period of time.

When the uterus is finally emptied of its contents three very apparent and important things take place. The depth of the uterine cavity, as measured by the distance that the curette enters, lessens perceptibly due to the contraction of the organ occasioned by stimulation of the manipulation and the oxytocic action of the pituitrin. The second change noted is that the uterine wall becomes thicker and firmer, and thirdly, there is decidedly less bleeding.

At this point it may prove of much interest to make an analysis of the pathologist's findings in the curettings sent to the laboratory. Immediately his findings permit division in two groups, non-inflammatory and the inflammatory. The former group contains villi, deciduæ and hypertrophic endometrium, either alone or in combination; the latter group contains inflammatory cells and exudate, degenerated and infected blood clots, white blood cell infiltration in combination with villi, deciduæ and hypertrophic endometrium. Out of 192 reports from the laboratory which are on record in this series, ninety-five would come in the non-inflammatory group, while ninety-seven would be classed in the inflammatory group.

With these facts arrayed before us, it becomes very difficult to regard any so-called conservative treatment which permits this material to remain in the uterus as being safe and sane. To allow this debris to remain in situ must invite an endometritis, prolong subinvolution and endanger the patient to a pelvic infection and invalidism. On the other hand, to remove this material removes a focus of infection; to allow the uterus to involute properly protects the patient against endometritis, myometritis, dysmenorrhea, menorrhagia and metrorrhagia, etc.; to control the uterine bleeding conserves the patient's energy and strength and enhances her chances for victory in her battle for restoration of health.

Furthermore, one must not overlook the fact that a hydatid mole with all its possibility of malignancy can arise from the chorionic villi of an incomplete abortion.

The post-operative results were very satisfactory. In the early part of this work I endeavored to keep all the patients in the hospital for a full week after curettage. But I became more liberal in this respect when some patients left the hospital earlier without any apparent bad results. The 235 patients in this series spent 1,625 post-operative days in the hospital, or an average of seven days each. Eighty-one per cent came in this group, while 19 per cent stayed longer than seven days, but the largest number only five days.

The American College of Surgeons, in defining post-partum morbidity, defines it as a condition of elevation of temperature to 100.4 during any two consecutive days post-partum, with the exception of the first day. While the post-operative state of these patients cannot rightly be regarded as post-partum, they have, nevertheless,

much in common. According to this definition I had thirteen cases of morbidity, or 5.5 per cent.

A further study of these cases is interesting. According to this definition they all exhibited a preoperative morbidity although the temperature may not have been as high or lasted as long as it did postoperatively. The average preoperative days of hospitalization in the morbidity cases was 8.75 days, while the post-operative hospitalization was 15 days, which figures are both much higher than the average for the whole series. The average number of days preoperative in which the morbidity patients were afebrile was 2.25 days; the longest was five days. Hillis emphasizes the value and importance of at least a 5-day afebrile period before operation and states that there is less postoperative fever if this is adhered to. Tuttle experienced that febrile cases operated on promptly had a higher average of postoperative febrile days.

One patient was in the hospital for seven weeks before operation with only four afebrile days and 25 days after operation with 17 afebrile days. Her convalescence was interrupted by an ice bag burn. Another patient had 3 afebrile days before operation and developed a pelvic abscess which was drained vaginally 17 days after curettage, following which she improved rapidly. These two cases exhibited the outstanding morbidity, 0.8 per cent.

I made several mistakes. While all of these curettages were done because of a diagnosis of incomplete abortion, the pathologist's report failed to substantiate that diagnosis in several cases. He reported chronic endometritis in one case; acute endometritis in two cases; normal endometrium in three cases; uterine muscle fibres in one case and necrotic mass in two cases. This last may have been the result of an incomplete abortion. I anesthetized one patient for operation who had a pedunculated submucous fibroid. One patient, as stated earlier in the paper, had to submit to a second curettage. There were no deaths in this series of 235 cases.

I regret that I did not follow the routine practice of making a pelvic examination before discharging the patient. The findings would have lent themselves admirably to a fuller discussion of this subject. Questionnaires were mailed but only fifty-six replies were received. Two sets of questions were asked. The first set dealt with the possible development of pelvic trouble as a result of the curettage while the second had to do with the patient's future pregnancy, if any.

Comparing and analyzing the answers of those whose reply suggested a possible pelvic pathology, I am not convinced that any of them suffered any bad results. Seven patients reported some bleeding after leaving the hospital; two no doubt had reference to menstrual periods while five of these reported a subsequent pregnancy, four of them miscarrying. Eleven of the patients thought that they had developed a leukorrhea, seven of these reporting a subsequent pregnancy, four going to full term. Five reported changes in their menses, three miscarrying when they became pregnant. Three reported pelvic trouble, of which one went to full term in her subsequent pregnancy and a bimanual examination showed a negative pelvis. Another one was in need of a pelvic repair which she has had done since then.

In the second set of questions, which dealt with a possible subsequent pregnancy, I find that 50 per cent of the replies received showed a pregnancy after the curettage, of which 63 per cent either went to full term or were pregnant when they answered the questionnaire.

This analysis, although not based on a large series, convinces me that a carefully safeguarded curettage for incomplete abortion does not lend itself as an etiologic factor in the production of pelvic pathology or sterility.

Conclusions.—Curettage of the uterus for incomplete abortion with a sharp curette, as was done in this series of cases, is a safe and justifiable procedure.

Certainty of diagnosis, a definite afebrile preoperative period of about five days and care in technic are very important.

To empty the uterus of its foreign and infected material, stimulating it to contract and controlling the bleeding, safeguards the patient, shortens her stay in the hospital, conserves her energy and enhances her chances of recovery.

Perforation of the uterus can be avoided and the danger of incompletely emptying the uterus is overestimated.

Digital curettage is an unsatisfactory and dangerous substitute operation.

PROPAGANDA FOR REFORM

Ampoule No. 61 Sodium Salicylate 15 1/2 Grains, Ampoule No. 66X Sodium Salicylate, Sodium Iodide 15 1/2 Grains Each, Ampoule No. 66X Sodium Salicylate, Sodium Iodide and Colchicine, and Ampoule No. 50 Iron and Arsenic (Iron Cacodylate) 1 Grain, Not Acceptable for N.N.R.—The Council on Pharmacy and Chemistry reports that these are included in the list of ampoules for intravenous use marketed by the Lakeside Laboratories, Inc., Milwaukee. In 1921, in reporting on "Some of Loeser's Intravenous Solutions," the Council stated the objections to the intravenous administration of sodium salicylate and sodium iodide and of mixtures of drugs in fixed proportions. Since this time no evidence in favor of the routine intravenous administration of sodium salicylate or of sodium iodide has been brought forward, and the objections to the fixed proportion mixtures applies to the mixtures listed in this report. Ampoule No. 50 Iron and Arsenic (Iron Cacodylate) is unacceptable because the name is nondescriptive; because recommendations for the routine intravenous use of iron are not warranted, and because iron cacodylate presents an irrational and useless method of the administration of iron and arsenic. The Council declared Ampoule No. 61 Sodium Salicylate 15½ grains, Ampoule No. 59 Sodium Iodide 15½ grains, Ampoule No. 66X Sodium Salicylate, Sodium Iodide 15½ grains each, Ampoule No. 66 Sodium Salicylate, Sodium Iodide and Colchicine, and Ampoule No. 50 Iron and Arsenic (Iron Cacodylate) 1 grain unacceptable for New and Non-official Remedies because recommendations for the routine intravenous administration of sodium salicylate and sodium iodide are not warranted and because the administration of sodium salicylate and sodium iodide, of sodium salicylate, sodium iodide and colchicine in fixed proportion and of iron and arsenic in the form of ferric cacodylate whether intravenously or otherwise is irrational. (Jour. A. M. A., January 4, 1930, p. 31.)

Excretion of Barbital.—Sir Maurice Craig holds that barbital preparations may be taken for years without producing deleterious effects. This view has received some experimental verification. On the other hand it has been held that in certain conditions—Manic-depressive insanity, constitutional psychopathic inferiority and psychoneuroses—its use may lead to habit formation and that to such patients these drugs should never be administered. (Jour. A. M. A., January 4, 1930, p. 35.)

Pituitary-Solution-Squibb 1 c.c., 5 Units, and Pituitary Solution-Squibb 1 c.c., 20 Units, Not Acceptable for N.N.R.—E. R. Squibb & Sons market Pituitary Solution-Squibb 1 c.c., 5 units, and Pituitary Solution-Squibb 1 c.c., 20 units. The first product is one-half the strength of solution of pituitary-U.S.P., while the second is twice the strength. The Council holds that it is not in the interest of rational therapy to market strengths different from that of the standard pharmacopeial product and therefore cannot give recognition to such preparations. Accordingly, the Council declared these Squibb preparations unacceptable for New and Non-official Remedies. (Jour. A. M. A., January 11, 1930, p. 105.)

Resuscitations and Intracardiac Injections.—The power to revive the dead is one that the physician is often, but vainly, expected to exhibit. The alleged miracles of such revivals by injecting epinephrine into the heart are always widely reported in the newspapers. Physicians who have heard of these alleged resuscitations are tempted to employ the same means. If the death was real, no harm and no benefit results. Revival follows sometimes, perhaps not because of the treatment but in spite of it. In such cases there is indeed grave danger that serious injury may follow from the treatment that the patient has received. The evidence seems conclusive that, if the patient revives after such an intracardiac injection, he would have revived without it. Intracardiac injection is not a justifiable measure for resuscitation. (Jour. A. M. A., January 11, 1930, p. 107.)

Cod Liver Oil Viosterol or Sunlight for Rickets.—Cod liver oil, viosterol and ultraviolet rays are generally accepted as specific agents in the prevention and cure of active rickets in infants. Their relative merits are still under investigation. Cod liver oil contains the valuable vitamin A in addition to vitamin D. Viosterol is of advantage because of the ease of administration and its concentration. Ultraviolet rays are undoubtedly a valuable therapeutic agent when under controlled supervision. Their effect on general nutrition and resistance as well as on the calcium retention is good. Their use to the exclusion of vitamin D or viosterol seems unwise. A combination seems most desirable when sunshine is not available. (Jour. A. M. A., January 25, 1930, p. 283.)

CORBUS' DISEASE

REPORT OF TWO CASES

A. Clifford Abbott, F.R.C.S. (Ed.)
and
George Ryan, M.D.
Winnipeg, Manitoba

EROSIVE or gangrenous balanitis was first described by Bataille and Berdal in 1889. Their work was confirmed by Scherber and Muller in 1904. The disease, however, was not recognized as an entity until Corbus and Harris, working in the United States, established it on a clinical and pathological basis as a fourth venereal disease. In 1909 they defined it as "a specific infectious venereal disease, caused by a symbiosis of a vibrio and a spirochete, with local and constitutional symptoms varying with the severity of the infection."

The disease is pratically limited to those of unclean habits. Predisposing causes are: (1) long, tight foreskin which excludes the air; (2) moistening the genitalia with saliva. As the organism is anaërobic, it can only occur in those who have not been circumcised. In most cases a history of unnatural sexual relations, or of moistening the genitalia with saliva may be obtained.

The specific organisms of this disease are a vibrio and a spirochete. Microscopically and morphologically they are identical with Vincent's organisms. Whether they are the same organism is still a debated point. They grow under anaerobic conditions on serum agar and stain with ordinary dyes. The vibrio is gram-positive and the spirochete gram-negative.

The pathology begins with an erosion usually in the sulcus coronarius. It spreads rapidly to the foreskin and glans, ulceration becomes widespread and gangrene of a large part or the whole of the penis occurs if not treated promptly.

These greyish and hollow ulcers may be single or multiple. There is itching and burning under the foreskin, but no pain on micturition. The foreskin may be retracted without difficulty and constitutional symptoms are absent.

As the condition progresses the ulcers deepen and become irregular in outline. They tend to become confluent, forming ulcers from one to one and a half centimeters in diameter. The bases are irregular and covered with a necrotic yellowish white or brown pseudo-membrane. The edges are clean cut and slightly raised. The foreskin is edematous and cannot be retracted. There is a thin, yellowish white foul discharge in which the specific organisms can always be found.

Venous stasis and thrombosis supervenes, due to the edema. The overlying skin becomes dark and finally black and necrotic. If not treated energetically the entire penis becomes involved in this process. The entire penis becomes enormously edematous, the dorsal lymph cord is palpable and the inguinal glands are enlarged. As a rule, however, they are not painful.

Constitutional symptoms at this stage are very often severe. Vomiting, headache, general malaise, chills and fever with a temperature of 100-101 are common.

If untreated the whole penis and scrotum becomes a black, sloughing mass. The patient gradually dies from toxemia.

Differential diagnosis is important so as to institute the proper treatment early. Chancroid may resemble it closely but does not spread with the same rapidity. Microscopic examination of the smears moreover show Ducrey's bacillus. Painful suppurating glands are common in chancroid, whereas in gangrenous balanitis the enlarged inguinal glands are painless and do not suppurate.

The hard chancre of syphilis comes on later and is more indurated. The type of spirochete may also be differentiated by dark field examination.

The treatment in the early stages is frequent cleansing and exposure to the air. When there is edema of any extent present, the preputial sac should be irrigated every half hour with some mild oxidizing agent such as hydrogen peroxide 2 per cent, or potassium permanganate 1/4000, until the condition subsides. This is done most conveniently with a Guyon catheter attached to an all-glass syringe. Cold applications of Dakin's solution in the intervals are excellent.

If the foreskin is gangrenous, enough should be removed to expose the ulcers freely. Some advise using the cautery for this purpose. A continuous irrigation, similar to the Murphy drip method, is commenced, the tube being fixed in a light dressing over the penis. Within forty-eight hours there is a marked improvement, both local and general. Any further necrotic areas slough away and the patient is left wholly or partially circumcised.

The following two cases are reported for the purpose of showing, in the first case, the usual course of the disease, and, in the second, some unusual and interesting features.

Case 1.—F. H., aged 28, was admitted July 2, 1928, to the observation ward at the Winnipeg General Hospital with pain, swelling and edema of the foreskin. The skin over the dorsum of the glans was quite black. His temperature was 100, but his general condition good.

Six days previous to admission his symptoms began with itching and burning under the foreskin. His symptoms gradually became worse until, after five days, the skin over the dorsal surface of the glans penis became black.

On admission the entire penis was edematous, the foreskin over the dorsum of the glans black and gangrenous with a thin and extremely offensive pus exuding from beneath it. The foreskin could not be retracted. A smear of the discharge showed spirochetes and fusiform bacilli.

He was put on alternate irrigations of hydrogen peroxide and 1/4000 potassium permanganate every half hour, cold compresses being applied continuously in the intervals.

By July 3, the gangrenous portion of the foreskin had sloughed entirely, exposing several large ulcers on the glans and sulcus.

In spite of a negative Wassermann, the patient was given .45 novarsenobenzol intravenously, and some of the novarsenobenzol powder was dusted on the ulcers directly. A continuous drip of 1/4000 permanganate was started. Temperature 100.6, general condition good.

On July 4, the ulcers appeared much cleaner. Temperature 99. Smears from the mouth reported positive for Vincent's organisms. The patient admitted moistening the penis with saliva.

The following day the temperature was normal, the ulcers were healing well and the general condition was good.

July 13. Temperature still remained normal. The ulcers were practically healed. The potassium permanganate drip was discontinued and the patient was allowed up.

By July 16 only very small ulcers covered with dry crusts remained. The patient has lost only that portion of the foreskin which was gangrenous on admission. He was discharged in good condition.

Case 2.—F. Z., aged 46, was admitted to St. Joseph's hospital Feb. 11, 1928, with a temperature of 102, pulse 128 and respiration 32.

The patient stated that ten days previous he froze his penis while working in the bush. The first thing he complained of following this was a soreness under the foreskin. He held a consultation with a fellow workman, who advised painting it with iodine. This treatment was carried out. The following morning the penis was very sore and very swollen at the end. This was one week ago and the swelling has progressed.

The penis was swollen up to the base to a diameter of 1.5-2 inches and was about six inches long. The skin was thick, edematous, firm and did not pit readily on pressure. A cough was present and the breath offensive.

I first saw the patient on February 13, twelve days after the onset of the infection. At that time the penis was tremendously swollen and the swelling and edema had extended over the entire front half of the scrotum. There was a slight seropurulent discharge from the under surface of the foreskin, but the edema was so great that the glans could not be seen. There was a small area on the dorsum of the foreskin which was dark in color. The man's general condition was very poor. His respiration could be heard over the entire ward and he was cyanosed. Percussion yielded no dullness but both lungs were full of coarse râles from apex to base. The heart was not enlarged but the heart sounds were of poor quality. The patient's temperature was 100, and his pulse ranged from 120 to 140.

It was felt that a dorsal slit offered probably the best chance of saving the penis, and this together with two incisions into the scrotum was made under sacral anesthesia at once.

In the first twenty-four hours following the incising, the actual nature of the disease was not recognized. Smears taken and planted in an anaërobic medium yielded a mixed growth of bacteria. The wound was fomented and the patient was put on brandy and digitalis. The afternoon of the operation the patient had a smart hemorrhage which was arrested without difficulty.

After forty-eight hours the condition was recognized as probably a very severe form of Corbus' disease. It was thought that the lung condition was an entirely different process arising from exposure and cold. Dakin's compresses and irrigations were commenced and fluids pushed to 3,000 c.c. daily.

Within seventy-two hours from the time of incision, the entire skin covering the penis and anterior surface of scrotum became black and gangrenous. At the end of the fifth day the whole mass sloughed away leaving the shaft of the penis completely uncovered and the testicles exposed.

The shaft of the penis was found to be necrotic also. It was evident that the penis was going to slough probably as far as the triangular ligament. The patient's general condition was extremely bad. The temperature varied from 97 to 103, pulse 100-140 and respiration 30 to 50 per minute. The patient was delirious at

least half the time. Examination of the chest revealed the lungs full of râles and some increase in heart dullness. The patient's condition was such as to prohibit any thorough examination.

On February 21st the penis dropped off level with what was apparently the triangular ligament (Fig. 1).

Fig. 1.

The Dakin's compresses were continued alternating with carbonlight and the wound gradually became quite clean and a mass of granulations.

The patient's temperature gradually subsided, his pulse came down to about 110 and his general appearance improved. On March 1, 1928, he complained of a sore thumb. It was tender on pressure and was dull red over an area the size of an American nickel. The spot was black by the next day and was incised and Dakin's compresses applied. The patient's condition remained unchanged until ten P. M. March 4th, when he suddenly died.

POST MORTEM FINDINGS (DR. O. C. TRAINER)

There has been a gangrenous process of the penis and scrotum which has resulted in a complete sloughing of the penis level with the triangular ligament and partial sloughing of the scrotum involving chiefly the anterior wall.

On removing the anterior chest wall a large abscess is seen to occupy the antero-superior part of the mediastinum, involving the pericardium and encroaching on the medial aspect of the right lung. This part of the lung is necrotic and partially sloughed away. The abscess is filled with a foul smelling necrotic mass.

Smears from the mediastinal abscess and from the genitalia show large numbers of a fusiform bacillus and a spirillum resembling Vincent's organism. Cultures showed mixed growth of staphylococcus aureus and streptococci.

These two cases are reported for the purpose of putting on record the latter case, in which apparently the original lesion in the genitalia gave rise to secondary infection of the lungs and mediastinum.

Although we were unable to grow the Vincent's organisms in the one culture planted, we feel that this is a true case of Corbus' disease.

VAGINAL STERILIZATION

Daniel H. Bessesen, M.D.
Minneapolis

A LARGE variety of pathogens have been found in the genital tract following delivery: *streptococci pyogenes* and *hemolyticus, staphylococcus pyogenes, bacillus coli communis,* gonococcus, pneumococcus, *B. diphtheriæ, B. typhosus, B. tetanus, B. erogenos capsulatus, B. pyocyaneus, micrococcus tetragenus, staphylococcus parvulus* and other putrefactive organisms as *B. funduliformis, B. radiiformis, B. proteus,* and anaërobic streptococci which have been held responsible for fever and death.

The question as to how these organisms enter the birth canal is important since with this knowledge it may be possible to prevent such entry. Many investigations have been made to determine the bacterial content of the vagina and uterus and show that these organs are, with few exceptions, free from pathogens. The uterus, cervix and upper portion of the vagina normally have no pathogenic content.

It has been demonstrated that the introduction into the vagina of any object, sterile or contaminated, will carry with it bacteria. This may be accomplished by the physician, nurse, midwife, or patient through vaginal examinations, douche nozzles or instruments. How much time is required for the vagina to resume its normal state, free from organisms, after contamination seems an unsettled subject. It probably depends on the number of organisms introduced, the virulence of the bacteria, the condition of the patient, and the condition of the generative tract, whether infected or filled with vegetative matter. Some authors recommend that the patient refrain from coitus during the last few days prior to labor: others, a period of six weeks. This must indicate that in the experience of these advisors, the introduction of contamination requires approximately that interval for control.

The present trend of obstetric teaching is to avoid the passage of any object into the field of labor for some period before labor, and presupposes that the lower uterine segment, cervix, and vagina are sterile when the patient enters the hospital. Still applying the same reasoning, all effort is made to see that the labor is attended by no vaginal examinations, and as little instrumentation as is compatible with the life and health of the mother and child, during that particular labor. If, then, infection occurs, it is stated that outside influence was responsible for the introduction of bacteria. If death from infection occurs, the statement is made that the attendant is responsible for the death. This, in spite of the fact that since the time of Holmes and Semmelweiss, a concentrated effort has been made to avoid introducing anything into the obstetric field.

In Lea's masterly review[1] of puerperal infection is given an extensive account of the deaths from this cause in England and Wales and a slightly lesser study of these deaths in various parts of Europe. In this country, a somewhat similar exposition has been made by McGlinn[2] and others. They show that 35 to 48 per cent of all maternal deaths are due to puerperal infection. Various explanations are made as to why infection follows childbirths, and is so severe as to cause many deaths. Even with the large majority of medical men graduating from first rate medical schools and with most of the obstetricians realizing that the entry of the vagina manually or instrumentally means infection, still infections occur. Not only do infections occur in cases subjected to vaginal interference but it also appears in some cases which are in every way delivered ideally. Death from infection is known to result where there has been no vaginal examination, no instrumentation, no accidents of labor and no lacerations.

We tend to blind ourselves by believing that the bacteria have been introduced before the patient came under our attention. But if such a thing has occurred, what does that mean to us? It means simply this,—we are dealing with an *Infected Field.* Every obstetric case that enters our professional care is potentially infected before we see the case on the delivery table. We cannot know beforehand what case will develop fever. The patient may deliver very promptly, with no apparent abnormality and subsequently die of infection. Is this the doctor's fault? Is

it the fault of the attendant when the best technic known is applied to a labor and the patient dies of infection?

Of course there are occasional epidemics of infection, such as occurred in the Sloane Hospital in 1927, which clearly implicate the attendant as an agent in carrying outside infection to the obstetric patient. But this again is a factor for potential infection which must be faced by every hospital in the country. Is there nothing that can be done to counteract the potential infection present in every obstetric case?

There are two sources of bacterial invasion in the parturient patient: (1) Infection present in another part of the patient's body which may spread to the labor wound (through blood, lymph or contiguity); (2) infection present in the birth canal (already present or introduced shortly before labor) which may spread to the labor wound. By careful prenatal attention, every effort is made to bring the mother through the period of gestation with the elimination of infection in any part of her body. Accurate instruction is given her how to avoid the possible presence of infection in the vagina previous to labor; and, finally, labor is so conducted as to minimize the possibility of bacterial invasion during parturition and puerperium. These efforts are not without their results, but an occasional case will slip through this close attention, and an infection result in a fatal outcome; and, to all appearances, this is in spite of the most religious application of our most advanced scientific management.

What is to be done with the potentially infected maternity patient? Every mother is potentially infected.

Every labor presents a wound. The woman's natural recuperative processes, especially in the usual absence of bacteria, result in complete return to normal in a few weeks' time. But if bacteria are present, the mother's resistance may be taxed to the utmost.

The character of the labor has much influence on a potential infection. The presence of toxemia in a mother is a known agent for increasing the possibility of infection. A long labor with need for surgical interference adds a few points to the already high percentage possibility of infection. Lacerations of all sorts in the perineum or cervix, both of which are such common points of stress during labor, open the weakened tissues to direct bacterial action. If the membranes rupture early, or there is a placenta previa or, from other causes, blood in the birth canal before labor, there is an increased likelihood of infection. The crushing of soft parts against a deformed pelvis, even without rupture of the uterus, may result in direct extension of infection to the peritoneum.

The type and number of organisms and the point of entry determine the localization and character of the infectious lesion—whether it be abscess, phlegmon or thrombus.

We know that with our best efforts to prevent infection, it will occur in a small percentage of all cases. Of the febrile patients, some will die. After the infection has started it is too late to expect to accomplish much by radical procedures.

The time to deal with puerperal infection is before the labor is accomplished, while we know we are dealing with a potentially infected field.

We would not undertake a surgical operation without first making every effort to destroy the bacteria which might gain entrance into the wound. Yet we deliver a patient, following which we know there will result a large obstetric wound through a field which we know beforehand may contain bacteria, without any effort to destroy the bacteria we suspect to be present. Studies on the aseptic vaginal examination show that after this method of procedure, the number of postpartum infections have doubled. Proof more positive could not be presented that these additional infections have come from bacteria already present in the vagina. Yet no effort is made to destroy these bacteria. We introduce a bag aseptically, dilate manually aseptically, perform instrumentation aseptically, and as a result treble the postpartum infections over what would be present in the normal spontaneous delivery. We can give no more certain evidence of the presence of bacteria in the vagina than these figures. The bag had on it no bacteria; the hand was gloved and sterile; the instrument certainly was not contaminated. What happened to double and treble the infections. Bacteria already present have been carried from the lower portions of the vagina to the higher levels—closer to the obstetric wound.

Yet these maneuvers are performed aseptically —not antiseptically. No effort is made to destroy these bacteria which are without question responsible for the additional infections in these cases.

Why should not a field which is not sterile, and is about to be the site of a formidable injury, with expectation of exposing the body to the ravages of micro-organisms which are known to be present, be rendered as sterile as the present knowledge of antiseptics will permit? Why is it considered unscientific to prepare a patient for an ordeal with the greatest protection we can offer—the destruction of the bacteria which may cost her life?

These questions have appealed to other observers in former times—Zweifel,[4] Schweitzer, Esch, Schröder, von Herff and others. Effort has been made to sterilize the vagina using douches and antiseptic preparations. Because these efforts failed, and some of them increased the percentage of infections, all attempts were dismissed as useless or even harmful. But a conscientious study of the actions of antiseptics on mucous membranes shows that the requirements of disinfection of mucous membrane are somewhat different from those that apply to the external skin. The antiseptic which sterilizes the skin may injure the mucous membrane, cause it to become swollen, parched, dry, cracked, fissured, and expose it to further invasion of the bacteria which unquestionably will grow again in larger form and numbers when nourished back to life (after the passing of the bactericidal action) by the excellent culture medium of the body fluids seeping through this injured mucosa heated to the optimum temperature of the body. When such a strong antiseptic was applied to the obstetric patient, it is little wonder that the number of infections increased. Another factor which has done much to wave aside any suggested further investigation of this field, by even the most courageous of scientific advocates, has been the very thing which first reduced the morbidity to its present figure—the work of Holmes and Semmelweiss. So thoroughly has their thought been impressed upon us, that we cling to the opinion that nothing—not even a suitable antiseptic—must be conveyed into the vagina.

This, however, is contrary to our own honest judgment. If we will consider a little, we must see clearly that an antiseptic non-injurious to the mucosa, non-toxic, bactericidal, introduced into the obstetric field often enough during parturition to destroy or vitiate pathogenic entry into the obstetric wound must reduce to a minimum any possible source of infection through the birth canal. We cannot prevent the spread of hematogenous, lymphatic or contiguous (ovary, tubes, etc.) infection when it is already present in the patient's body, and the obstetric wound is open, offering such splendid pabulum to circulating organisms.

It remains for us then to consider the subject of the preparation of the obstetric patient for the delivery of the fetus. The manner of preparation is sometimes fruitful of trouble. In some hospitals, one observes that after shaving the perineum, the abdomen, thighs and perineum are carefully washed with soap and water: the excess of cleansing fluid is flushed away by pouring water over the abdomen, thighs and perineum. Finally, this water is poured over the vulva. If one inserts a speculum into the vagina after such a preparation, water will be found in the vault of the vagina. This water has entered through the introitus, carrying with it bacteria from the vestibule, labia binora, majora and clitoris. For this reason, a sponge must be held over the introitus so that no cleansing fluid enters the vagina. The antiseptic is painted on beginning with the labia minora, and is applied laterally, in either direction, until the entire perineum and portions of the abdomen and thighs are well covered. The attention to the anal region is last given and no other part of the skin is touched with that sponge, once the anus is touched. If more antiseptic is desired, a clean sponge is taken.

The labia minora (which have been painted) are carefully separated, and the vestibule is thoroughly saturated with the antiseptic. Finally, a clean sponge soaked with antiseptic in inserted into the vagina just at the aperture. Then with sterile gloved fingers separating the vaginal aperture antiseptic fluid is introduced into the vaginal canal, and the gloved sterile fingers work this well into the mucosa of the entire vagina. This application may be made through a speculum if so desired, as the leaves of the speculum iron out the rugæ of the vaginal walls. If labor continues for any length of time, this preparation must be repeated every eight to twelve hours, depending on the type of antiseptic and the length of its action.

A study of the various types of antiseptics shows that at present the most advantageous drugs for mucosal sterilizing are hexylresorcinol and mercurochrome. Recently a product known

as merthiolate has been advanced with experimental data that place it on a par with those mentioned above. Hexylresorcinol depends for its action upon its physical properties, and will not act unless it comes in contact with the bacterium in sufficiently strong solution to dissolve the germ. Mercurochrome, and apparently merthiolate, depends upon chemical action, and is germicidal in very weak solutions. For this reason I have utilized mercurochrome, though other men, engaged in the same effort, have apparently secured equally good results from hexylresorcinol. No clinical application has as yet been made of merthiolate.

Harry Mayes[3] has developed a technic using 4 per cent aqueous solution of mercurochrome and painting this over the perineum and introducing 4 c.c. into the vagina, working this in gently with the gloved fingers.

My own method, started before I was aware of Mayes' work, is to paint over the perineum a 10 per cent solution of mercurochrome, and introduce into the vagina a solution of glycerine (5 c.c.) containing enough mercurochrome to make 5 per cent and iodine 1 per cent.

Other methods have usually made use of iodine solution over the perineum, removing this with sodium thiosulphate or alcohol, or using alcohol alone over the perineum, but these drugs are too irritating to introduce into the vagina.

From the figures presented by Mayes and his co-workers and from my own experience, the morbidity in obstetrics has been reduced one-half or more.

It is to be recognized that the ideal method of antiseptic preparation has not been produced. What we have at present to work with may not be properly applied. Both the technic of application and the drug itself will be changed in the future advance of scientific attainment.

Summary.—We have attained the highest excellence in our methods of preparing our rooms, instruments and apparatus. We are most exact in the management of labor, but we fail to remove from the birth canal the pathogenic bacteria which are present in a few cases. After shaving, cleansing and sterilizing the perineum, by introducing into the vagina antiseptic solutions, mild enough to be non-injurious to the mucous membrane, but strong enough to kill or vitiate pathogenic bacteria, by repeating this application often enough to allow no recovery of the bacteria during labor we may leave to the maternal body an easier recovery, with less likelihood of postpartum infections as shown by the consideration given in the above discussion.

Conclusions.—There is need for more investigation along the lines of antiseptics for use on mucous membranes. If an efficient mild antiseptic, non-injurious to the mucosa but bactericidal, is applied to the perineum, vulva, and vaginal mucosa, and repeated at intervals during parturition, infections during the puerperium will be reduced approximately 50 per cent.

WHEN IS A HYPERPLASTIC SINUS, AND WHAT? AND ITS PARALLEL, THE MUCOID EAR

W. W. Lewis, M.D., F.A.C.S.
Saint Paul

THE title of this paper is, I believe, the feeling of the majority of the profession and, too, of the average rhinologist insofar as the application of his knowledge of the condition goes, in ready, definite clinical recognition and correct estimation of so-called hyperplastic, non-suppurative paranasal sinus disease.

Many years, successively, of groundwork and preparation under competent control, of continuous fraternal contact in the specialty, and with average intelligence, maybe, have failed to qualify me to the extent of being able to pronounce a nose "positively negative" after examination by the usual, accepted methods; and I believe that internists generally are beginning to feel that way toward others upon receiving such report from their rhinologist consultant.

A nose that shows little or nothing by clinical inspection, anteriorly and posteriorly, either before or after shrinkage, or after suction, by puncture and irrigation, or definitely enough by transillumination, or even by simple, unaided radiography, but may still hold a diseased sinus which is a depot of poisoning, has long been a constant dread to many of us, largely as a result of Sluder's writing concerning posterior nasal pathology, but never so thoroughly appreciated until the advent of iodized oil in radiography.

The culprit in this blind, blank chapter of rhinology has been the non-suppurative, so-called hyperplastic sinusitis, better named, I think, mucoid sinusitis, at least in part of its course, and, like its parallel condition, mucoid otitis media, a bugaboo, also, in otology.

Neuman, several years ago, in spite of considerable contradiction by his fellow workers in Vienna, established well the separate clinical entity of mucoid middle-ear disease and its altogether different needs, both in recognition and handling, from the serous and suppurative forms. His demonstrations were positive and indisputable in diagnosis and treatment, and I am sure have never been forgotten by any member of his classes.

When this great difference in middle-ear affections is so manifest by direct visibility and in experience in handling them, surely, then, a parallel condition is to be met in anatomically and physiologically corresponding structures; and it does exist in the nose, but recognition is infinitely more difficult and, comparatively, largely by deduction, and its satisfactory treatment is correspondingly difficult.

This parallel condition in the ear, so much more accessible for observation and study, can better be considered at the outset.

Serous exudate in the middle ear, if it stops short of suppuration, is absorbed with comparatively little damage to the sound-conducting mechanism; and hearing acuity, upon each inflation, is immediately restored.

A suppurative exudate, too, even if not liberated by paracentesis, will liberate itself by localized necrosis and rupture of the drum; and, though it does some damage to the sound-conducting mechanism, yet recovery is comparatively complete, including hearing acuity, in the majority of cases.

With the mucoid exudate, on the other hand, different from the other two types in every way, the hearing acuity is not restored, nor even improved, in inflation. Neither will it liberate itself by spontaneous rupture. It will, unless removed by incision of the drum and forceful suction, remain permanently in the middle-ear spaces, to organize later into that most fatal condition to the hearing function known to us all as adhesive process, which collects the largest toll of all otitic pathology and for the most part is responsible for that ever-increasing army of the "hard of hearing."

The mucoid ear, like the mucoid nasal sinus, only too often goes unrecognized by otologists, not to mention pediatricians and general practitioners. The dull, gray drum, slightly thickened and a little leathery, with little noticeable congestion, but with partially obscured markings (short process, umbo and folds), is the picture of this very mucoid ear that slips by unrecognized until

it is irretrievably too late to save its hearing acuity.

If this functional damage, above considered in the ear, were all there was to be confronted in consideration of the condition both in the nasal sinuses and in the ear, but especially in the former, it would be a small matter as compared to the far-reaching systemic damage complicating its existence in those two localities.

Except in local or neighboring pathologic processes the mucoid ear, as well as the mucoid sinus, according to my observation, experience and belief, is responsible for tremendously more systemic poisoning than is the suppurative form of disease.

The presence of suppuration in itself indicates at least attempted local defense on the part of affected structures, which also means helpful protection for the whole systemic organism. But no such apparent local inflammatory process of defense is in evidence in mucoid disease of either the ear or sinuses.

To be sure, suppurative metastases do occur at remote localities as a result of suppurative ear and sinus disease, but not to the extent that low-grade systemic poisoning is seen in chronic arthritic disease, neuritis, myositis, low-grade iridocyclitis, and so on, which to my mind is due to the largely unsuspected mucoid affections so difficult of recognition, especially in the paranasal sinuses.

What is more common to the otologist of experience and to the pediatrician than to see low-grade arthritic symptoms in children clear up promptly upon the recognition and relief of an unsuspected mucoid middle ear, with no other evidence than a "dull, gray drum, slightly thickened and a little leathery, with little noticeable congestion, but partially obscured markings"?

And, similarly, this is, I believe, the condition in the nasal sinuses, almost impossible of recognition, that, existing indefinitely, is often responible for progressive arthritis deformans, upon which in such cases rhinologist after rhinologist has reported "nasal sinuses negative."

Dean's writing, more than anyone else's, has resulted in attentive observation in these cases on the part of pediatricians. One sentence by Sluder, in the preface of his book, "The cessation of nasal suppuration is not always the cure of the case," has volumes of significance in the consideration of this subject, and fits perfectly into my conception of mucoid-sinus disease.

Hajek, in his book, speaks of hyperplastic sinusitis in connection with ethmoid disease only, and I think most of us, likewise, think of it only in that connection and, too, mostly as a bone process where such pathology is comparatively easy of recognition and demonstration, clinically as well as in the laboratory.

That such hyperplasia in bone, as well as in soft tissues, does take place in the other sinuses, too, has been brought out best and for the most part by Sluder. And while bone involvement, in consideration of headaches, may be a matter of "specificity of locality" (pressure upon neighboring structures), yet in consideration of systemic toxicity the process is simply a matter of pathologic activity (retention, chemical change, decomposition, absorption).

Nor is genuine hyperplasia localized necessarily to the ethmoids or to any one portion of the nasal surfaces, for Onidi and Wright, in the laboratory, show that the same pathologic process is found in the region of the bulla and uncinate process. That ozena and atrophic rhinitis are the end-result of such pathology, disseminated over sharply defined portions, or throughout the entire half or whole of the nose, corresponding to the portions adjacent to affected sinuses, would seem to be the most acceptable conclusion. As atrophy in all tissues begins just one step beyond ultimate or extreme hypertrophy, likewise it would follow that hyperplasia, which is really more rapid and more unstable hypertrophy than the usual form of hypertrophy, would be a point of election for subsequent atrophy.

It is further pointed out that nowhere else in the animal organism is bone and its periosteal covering so closely adjacent to chronically diseased surfaces as in the nose. As a consequence, the periosteum, which is the most essential nutritive medium of the bone as a whole, very soon reflects its own involvement in the disease process by the ensuing atrophy of the whole structure.

The presence of polyps and polypoid tissue in the nasal chambers by direct inspection might point, by deduction, to a corresponding condition in the adjacent sinuses, but, inversely, the difficulty is that the absence, by direct inspection, of visible disease in the nasal chambers, in the early stages of the disease, would not and can not exclude the existence of a hyperplastic or mucoid process that may be found in the sinuses, which

is so frequently not suspected by the average rhinologist. This difficulty in recognition, frequent enough in anterior nasal disease, is, of course, much greater in posterior nasal conditions.

Wright's description, in Sluder's book, of the process of spongification and absorption of normal bone in the nose, with replacement by new scar tissue of hyperplastic change, fits perfectly, it seems to me, with the accepted idea of the change in the bony capsule of the labyrinth in otosclerosis, and adds much to the parallelism of the condition in these two localities. The two localities, after all, are one and the same system of mucous-lined air spaces, and must be susceptible to the same pathologic changes.

Nasal pathology, at least in our section of the country, is mostly the result of the unnatural, precipitate change in the atmospheric-temperature living conditions that we are subjected to in going in and out of our superheated living apartments, where an alternating temperature of sometimes as much as one hundred degrees' difference is experienced between in- and out-of-doors; and where the nasal mucosa in its attempt to adjust itself to such abuse becomes so thickened and hypertrophied as to close off normal ventilation and drainage of the surrounding, communicating sinuses.

The symptomatology of this non-suppurative mucoid affection, especially in the nose, being so meager as it is objectively, largely resolves itself into subjective complaints of the patient. Except in the presence of acute rhinitis or coryza, the patient's story of long, continuous, partial obstruction in his nose, alternating from one side to the other, spoken of by the older rhinologists as intumescent catarrh, should lead us to suspect early hyperplastic disease. And the "hay-fever" patient who has his "hay fever" at intervals the year round should be carefully considered likewise. The recurring water-logged nose of the so-called "vasomotor rhinitis" patient should also be thought of as having a possible hyperplastic or mucoid sinus at the bottom of his trouble.

Post-nasal dripping, so bitterly complained of by patients who, upon inspection, show no pus or recognizable secretion, is often described as an irritation that keeps them hawking and spitting and swallowing until their pharyngeal muscles cramp, which, though not recognizable even to them as pus or even mucopus, is nevertheless such an irritant to their soft palate and pharynx that in its path a scalding sensation is felt, as if a corrosive substance had trickled over these surfaces. The complaint of a watery drip from one nostril occasionally when stooping over, with or without an odor to the patient, which sometimes excoriates the outside skin, is a much less frequent story, but is occasionally heard.

Morning headaches, upon awakening, which are always noted by the observing patient as associated with the occurrence of transitory obstruction in one certain side of the nose, but which, nevertheless, occur independent of an acute rhinitis and without any sign of pus discharge, are likely the result of a mucoid sinus affection, and most likely of the maxillary. The midday headache of frontal sinus disease, without any sign of pus, and the occipito-nuchal headache of sphenoid disease, where repeated inspection fails to show any suppurative discharge, are also very likely of the mucoid type. And these patients frequently experience a startling and unannounced mucous coagulum of considerable size slipping into their nasopharynx, which, when in a recumbent position, brings them to their feet to expectorate it.

Whether the ultimate toxicity of mucoid sinus diseases is from bacterial toxins direct, or the subsequent chemical poisoning from retention and decomposition, I do not know, but it is generally believed that a parasite that will thrive in mucous secretion must be a rugged and hardy organism, for mucous is regarded, I believe, as bacteriocidal. At any rate, the systemic poisoning is most virulent, as seen in children especially, and, too, in adults.

I have particularly in mind a patient who, with trigeminal neuralgia (tic douloureux), had been in almost constant pain seizures for many days, and who was promptly relieved by the evacuation of a large mucous coagulum from the maxillary sinus of the side opposite her tic. She remained free of her trouble for seven months, when she again was relieved of the tic by evacuating a mucous coagulum the size of the white of an egg from the opposite maxillary antrum.

We have many records of patients whose low-grade arthritic symptoms have promptly ceased upon the relief afforded by antrum

windows and resultant ventilation and evacuation of mucoid accumulation.

I have a patient who, unaided, by snuffling and struggling as best he could, drew a mucous coaglum from some sinus on the right side of his nose which completely filled his mouth and, when expectorated into his cupped hand, filled it to overflowing, comparable in amount to the white of a large egg.

The prompt subsidence of systemic symptoms in children, where incision of the "dull, gray drum," followed by forceful suction, has evacuated the retained stringy mucoid mass, has been observed so many times in our experience that we feel ready to gamble on the result.

Cases of alleged hay fever and alleged vasomotor rhinitis, with definite asthmatic symptoms which are also fully relieved, so frequently get such entire relief by high septum resection, reaching to the roof from front to back, that we feel anxious to recommend it in all such cases where the crowding in the upper half of the nose is even but half of that for which in the early years of my practice I would have felt justified in recommending it.

Many times, in such crowded noses, one is astonished to find a "dog-ear-like" middle turbinate, with the bone of it entirely absorbed, and other evidences of end-results of hyperplastic process that ordinary inspection gave no hint of, including clusters of little bead-like polyps. The relief from headaches, as well as asthmatic symptoms, in these cases is usually surprising to patient and operator, and, what is most agreeable, resection of more than the submucous structures of the septum seems unnecessary, for with room and ventilation the rest clears up of itself.

No surgical procedure in rhinology, according to our experience, is capable of such a spread of beneficial application as high septum resection, reaching to the roof from front to back, in these diseased, crowded upper-half noses, where surprisingly much unseen pathology may be found after such resection, but which previously was not visible and could not be seen even with all possible shrinkage. Rarely does ethmoid or sphenoid disease exist without involving both, and the high septum resection proves equally beneficial to either and to both. The bony and cartilaginous septum may be as straight as a plumb line, with the lower half of the nose amply open, yet the upper portion of the septum be so thick and broad as to tightly wedge itself between the other structures. So long as this condition exists in these diseased noses, resolution, or even improvement, is impossible; nor is any other but most destructive surgical procedure possible.

To repeat what I stated before, the high septum resection alone is very often the only procedure necessary to get complete relief in these cases, where, without the loss of any mucous surfaces, it is, above all others, the operation of choice; especially since local (bloc) anesthesia is so perfect for its performance. Anything short of high resection, from front to back, of the upper half of the septum in these cases will not bring the desired result.

The treatment and handling of these mucoid affections, both in the nose and in the ear, we believe to be best met by conservative surgery. Exenteration usually has no place in its application to any of the involved structures (including even the ethmoids) unless it be in case of a mucoid-mastoid labyrinth, which generally has a history of long standing, non-painful involvement. Such a patient, following an acute, low-grade otitis media, with a leathery drum which does not rupture and has little and often no discharge after paracentesis except by forceful suction, fails to recuperate his well-being and continues hard of hearing in that ear. Aside from these, his sole complaint is that the side of his head feels dull, heavy and "woodeny." Occasional neuralgia-like, shooting pains are felt in the temporal region, and deep tenderness can be elicited upon firm pressure over the mastoid. Generally these mucoid mastoids show pathology of a most unexpected extent, almost unbelievable from the mildness of their symptoms, both objective and subjective.

The process limited strictly to the tympanic cavity, aside from the continued loss of hearing, gives the patient little concern after the onset, and will continue indefinitely for weeks without rupture and discharge, showing only a dull, leathery-looking drum. If the process is not recognized, and the drum is not incised, followed by forceful suction to evacuate the mucoid contents of the tympanum, the deafness will become permanent as a result of the hard, glue-like organization of the mucoid exu-

date, and the picture of extreme adhesive process will be complete.

This mucoid process in the frontal sinus, according to our experience, has been very hard to recognize. Cases that have the unmistakable midday pain of frontal sinus trouble, but do not show pus, are likely of the mucoid type, and we have opened frontal sinuses by external operation which have contained this same mucoid (not pus), egg-albumen-like material under pressure. Enlarging the normal passage from the frontal by judicious use of the rasp, if you are fortunate enough to have it remain free and open by postoperative care, is the only intra-nasal procedure available, and usually suffices, supplemented by proper suction, until ventilation accomplishes its benefits.

The ethmoids, if not altogether polypoid, in crowded upper noses so often do perfectly following high septum resections, which gives ample room, that we look for the most gratifying results as a routine.

The sphenoids, along with the posterior ethmoids, also do so well following high septum resection to its posterior limit that opening the face of the sphenoid is not done until we observe the results of the former simple procedure.

The antra of the maxillaries are usually adequately taken care of by large windows under the inferior turbinates, after the anterior end is nipped at its attachment to the side wall and is moderatey hinged upward. The window should be as low as possible, but this is hard of accomplishment owing to the ruggedness of the ridge at the floor of the side wall; and even if lowered to the utmost is not low enough to get away from the rather deep catch-basin form of the antral floors, which hold such considerable residual quantity of discharge.

Irrigation, in these mucoid sinus affections, according to my belief and experience, is only an added liability, for in case of the antra and sphenoids the irrigation water only adds to and favors absorption of the residual mucilaginous secretion, which is contrariwise to the most advantageous state of the cavities for resolution and recovery, unless it be completely removed subsequently and these catch basins be left dry, which is very difficult of accomplishment. A water-soaked sinus mucous membrane only adds to the difficulty and is least favorable to resolution.

Suction properly carried out, it seems to me, is a most beneficial and effective therapeutic supplementary procedure after providing ample drainage and liberal ventilation, for in the beginning it is the shutting off of these very essentials that leads to the pathology under consideration.

Suction as ordinarily administered in our offices is most inadequate for the best results. The cannula, directly placed by the operator into just the place where he wishes to use suction, is, of course, not what I mean. But suction as usually and generally attempted at the nostril entrance, and which causes negative pressure in all the nasal cavities on both sides with the pulling-up of the soft palate, needs to be continued much longer than we give time to such procedure in our offices.

It is our habit to instruct the patient how it is accomplished with the ordinary water pump, which he can purchase inexpensively and attach to the water faucet at home. In this way he can continue its use for half-hour periods once or twice daily after drainage and ventilation have been provided for surgically. Suction under the patient's own control is less painful and alarming to him, and far more effective when used for longer periods of time than we ourselves would devote to it in the office; and, in addition, the passive hyperemia that he gets in the diseased sinus from such lengthened treatments is very beneficial, even if the evacuation of the cavities is accomplished in less time than the period during which he continues the suction. And it is a job that we are very happy to relinquish to anyone who can do it as well or better than we can do it in the office.

As in the comparatively recent past the blanket diagnosis of syphilis for much ophthalmological pathology has given way before our understanding of focal infection, and, too, in like manner, rheumatism has been wiped from the board, the ever-decreasing designation of cases as hay fever, vasomotor rhinitis, and so on, will, I believe, be very much thinned down by our recognition and full appreciation of non-suppurative mucoid nasal and aural disease.

CASE REPORTS

POISONING FROM CINCHOPHEN*

LEDA J. STACY, M.D.
Division of Medicine, The Mayo Clinic
and
FRANCES R. VANZANT, M.D.
Fellow in Medicine, The Mayo Foundation
Rochester, Minnesota

A married woman, aged fifty-two years, presented herself at The Mayo Clinic in December, 1929, on account of intense jaundice of one week's duration. She had been seen first at the clinic in August, 1922, with a history of menorrhagia and intermenstrual bleeding for two or three years, and pelvic pain for several months. Examination disclosed moderate hypertension, and an epithelioma of the cervix of the uterus which extended onto the posterior vaginal wall. The fundus was large, firm and tender. A specimen taken from the tumor was diagnosed as squamous cell epithelioma, graded 3 according to Broders' classification. Radium treatments were given and a total of 3,500 milligrams hours was used in five doses at intervals of a few days. Because of very severe inflammatory reaction in the pelvis, treatment was discontinued. Subsequently the reaction subsided, the vaginal discharge and bleeding stopped, and the patient's health seemed excellent.

The patient returned to the clinic eight months later for observation. She felt well, and examination revealed nothing of significance save moderate hypertension. There was no evidence of any local activity of the malignant condition and the uterus was still large, but soft, with apparent fixation in the right side of the pelvis. She returned again in December, 1928, for examination. The vault of the vagina was sealed off and smooth. The uterus was still about two and one-half times the usual size, and movable. The hypertension had increased and the patient weighed 205 pounds.

From 1923 to 1929 the patient had enjoyed excellent health. During the summer of 1929 she had suffered with neuritic pains in the right thigh, over the course and distribution of the sciatic nerve. Because a friend had found cinchophen effective in relieving pain, the patient had started taking the drug and for six weeks she had taken one to three tablets of cinchophen daily. She finally had discontinued the medicine because of the appearance of nausea and vomiting which had developed a month after she had begun to take the drug. A week after she had stopped taking cinchophen, jaundice had appeared suddenly, concomitantly with an attack of diarrhea which had lasted only a day. The jaundice had been intense from the beginning and had not fluctuated. There had been no purpura or pruritus. Her home physician referred her to the clinic. He had found that her liver was enlarged but that it was smooth, not nodular.

The patient's skin and sclerotics were bright orange-yellow. Her nutrition was good and she felt well except for nausea. The systolic blood pressure in millimeters of mercury was 200; the diastolic, 110. The liver was just palpable on deep inspiration and in the course of the next few days it rapidly became smaller. Subsequently, it could not be felt. The spleen was slightly enlarged. The vault of the vagina was sealed off by dense scar tissue. The uterus seemed a little large, but was freely movable. There was slight infiltration of the broad ligaments. The neuritis had disappeared; there had been no pain since the beginning of the jaundice.

The concentration of hemoglobin was 72 per cent. Erythrocytes numbered 4,600,000, leukocytes 11,000, and platelets 120,000 in each cubic millimeter of blood. The urine contained a trace of albumin, a faint trace of a reducing substance, granular casts, and thirty-six leukocytes to the low power field. The concentration of blood urea was found to be 48 mg. in each 100 c.c. and that of the blood sugar, 87 mg. The coagulation time, as determined by the Lee method, was at first normal, but later was prolonged to twelve minutes. The van den Bergh reaction in the serum was direct, and the concentration of serum bilirubin, 39 mg. in each 100 c.c. Bile was not found in the stools, and repeated duodenal drainage failed to recover more than the faintest possible trace of color in the duodenal contents.

The patient was given a diet high in carbohydrate, calcium lactate in large doses by mouth, calcium chloride, and solution of glucose intravenously, both with and without insulin, but her condition grew steadily worse. The level of the serum bilirubin remained constant, the area of hepatic dulness as determined by percussion became smaller daily and she soon became drowsy and unresponsive, rapidly sinking into a typical state of hepatic coma on the fourth day after admission. She died on the ninth day, sixteen days after the onset of the jaundice, with terminal hyperpyrexia and signs of bronchopneumonia.

At necropsy, the liver was found to weigh only 903 gm., and it showed the typical gross and microscopic picture of acute yellow atrophy. There were small, petechial hemorrhages on the mitral valves, pleura, and mucous membranes of the stomach and jejunum, and there was evidence of terminal bronchopneumonia. Malignancy was not found on section of the uterus, cervix or vagina, but there was an increase in the fibrous connective tissue, compatible with the usual

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

after-results of radium irradiation. There was a small, irregular mass in the right broad ligament, involving the right ovary, which had completely obstructed the ureter and produced right hydronephrosis. Section of the ovary revealed a hyaline necrotic mass, with regions of calcification, occasional epithelial pearls, and a few mitotic figures. However, in that portion of the mass nearest the pelvic wall, there were many mitotic figures, indicating active malignancy.

COMMENT

The case is of interest in part from the standpoint of control of malignancy with radium. Although the cervical epithelioma was considered inoperable when the patient was first seen, and she received considerably less than the usual initial dose of radium, she remained free of symptoms for almost seven years. The pain which then developed suggested pressure on the sciatic nerve, although bimanual pelvic examination failed to demonstrate infiltration in the broad ligament or enlarged iliac lymph nodes. At postmortem examination it was noted that the portion of the mass which occupied the position of the right ovary contained cells which microscopically appeared to be of low grade activity whereas the portion furthest removed from the site of the original growth and from the radiated area was made up of cells of extremely malignant appearance.

In more recent years, it has been our custom to give deep roentgen-ray treatments once every three months for at least a year following the initial radium treatment in order, if possible, to destroy the outlying carcinomatous cells which might later became reactivated, as they seem to have done in this case.

The fatal outcome in this case was related to the recurring malignant condition in that the pain which it produced occasioned the taking of cinchophen, which caused the fatal intoxication. The drug can be readily obtained without prescription. The patient continued to use it freely for at least two weeks after definite toxic symptoms had appeared. Stopping the taking of the drug in no way checked the rapidly developing hepatic atrophy. The course of the illness is typical of the course in the fulminating type of yellow atrophy of the liver. The clinical picture is usually that of a rapidly progressive, painless jaundice with gastro-intestinal symptoms of which nausea and vomiting are the most common. In fatal cases, the patients sink into a terminal comatose state after an average of about two weeks, whereas if patients recover, icterus may persist for six weeks to two months.

The destructive process unquestionably continues for many weeks after the drug is completely eliminated from the body. Therefore, while it is important to stop the drug immediately on the appearance of any toxic symptoms, prompt recovery should not be expected in every case.

In the absence of any specific treatment, general supportive and symptomatic measures should be utilized. Since it has been shown repeatedly that an abundant supply of carbohydrates protects the liver from such poisons as chloroform and phosphorus and accelerates recovery from the hepatic injury induced by these poisons, it is rational to force the intake of carbohydrates by mouth, by proctoclysis and by vein. According to Minot and Cutler's work, calcium likewise has a protective action for the liver. Given by mouth or intravenously its use seems logical, and certainly does no harm. It must be admitted, however, that the measures now employed in the treatment of cases of acute yellow atrophy are most inadequate and apparently influence the outcome very little.

SODIUM AMYTAL IN CESAREAN SECTION

REPORT OF CASE

J. R. Sturre, M.D.
Minneapolis

Sodium amytal has been previously used in cesarean section. In reviewing the literature I find that Mendenhall[1] reports an hysterotomy on a woman in toxemia with convulsions, with a dead six months fetus.

In another report, Mendenhall mentions that several cesarean sections have been done. However, he does not go into detail in these reports on the effects of sodium amytal on the fetus. His first report deals with a dead fetus, so that, in this respect, this hysterotomy can be considered a laparotomy.

There has been much controversy locally on the effect of sodium amytal on the fetus, when used in obstetrics. It is claimed by some that the babies are depressed and hard to resuscitate. Believing that sodium amytal could be safely administered to a pregnant woman without injury to her fetus I employed this drug in the following case.

This woman, aged 22, a twin and a primipara, weighed ninety-eight pounds when first seen in the second month of her pregnancy. Her pregnancy was normal in every way throughout.

Her physical examination was normal except for her pelvic measurements.

Her family history was negative. Her twin sister is living and well.

Pelvic measurements: Int. Sp. 23—Int. Cr. 25—Ext. Conj. 17—Int. Conj. 8—Bi. T. short 7—Ant. Sag. 7—Post. Sag. 8. Baby estimated at eight pounds. The patient's weight at term was 132 pounds.

Labor began at term at 8 p. m., Feb. 4, 1930. She entered the Midway Hospital in St. Paul at 3:30 a. m. Feb. 5, 1930. Contractions were regular and severe, occurring every few minutes. She had an acute cold and was coughing considerably. Rectal examination was made at this time and the cervix was found to be dilated to a breadth of two fingers and the head not engaged.

At 4:30 a. m., one hour later, the findings were still the same. At this time 1 Gm. of sodium amytal was

dissolved in 10 c.c. of distilled water and 7.5 c.c. were given intravenously. She went to sleep immediately. Her pains continued regularly and at 5:30 a. m., one hour after the administration of the sodium amytal, she was sent to surgery for cesarean section. Here I picked up her skin on the abdomen with an Allis forceps and closed them to the second catch on the instrument and made traction on the skin. There was no evidence of sensation.

A very small amount of nitrous oxide was given with 60 per cent oxygen. The cesarean was completed in twenty-two minutes.

On incising the uterus, a small uterine incision was made. Through this the baby immediately presented an arm by its own muscular action. I placed this arm back into the uterus and, inserting my hand, grasped a foot and extracted the baby by version. The child was very active and cried immediately as the head was brought out. The thighs had to be held out of the way as the cord was clamped because of the baby's active movements. The color of the child was pink. There was absolutely no depression in any manner and no respiratory embarrassment at this time or later. The baby weighed exactly eight pounds.

The mother's uterus contracted at once and bleeding was not more than moderate.

In reporting this case I am not attempting to prove anything. However, because I can find no similar case that has been reported in full giving the effect of this drug on the child, I am making this report. In my case the drug was given over an hour before operation was begun. This gave time for maximum absorption of the drug by the baby and not sufficient time for recovery on the baby's part from any depression which might have resulted.

Nitrous oxide was not necessary but was given to insure that the patient would not rouse enough to interfere with the operation. However, the anesthetist said she did not give her enough nitrous oxide to make her dizzy.

Oxygen was given for obvious reasons.

Assistance was rendered by other members of the surgical team, consisting of Dr. N. P. Bentley, first assistant; Dr. A. M. Smith, second assistant (interne); and Miss Helen Cook, R.N., anesthetist.

EFFECTS OF CINCHOPHEN

Purpuric, urticarial, or scarlatiniform eruptions have been reported by many observers following the administration of cinchophen. They may occur with or without edema. Gastro-intestinal disturbances, from epigastric discomfort to acid eructations and heartburn, are the commonest expression of intolerance to cinchophen. These may be avoided by the giving of an abundance of water with the drug, and 1 Gm. of sodium bicarbonate, though the latter should be given separately and not mixed with the drug. By using neocinchophen, one may avoid usually the symptoms of gastric irritation. Sometimes cardiovascular disturbances have been noted. By far the most serious results of cinchophen intoxication result from injury to the liver, which may even go on to a fatal acute yellow atrophy. (Jour. A. M. A., January 25, 1930, p. 283.)

QUICAMPHOL (TRANSPULMIN) NOT ACCEPTABLE FOR N. N. R.

In 1927 the Council on Pharmacy and Chemistry considered Transpulmin, offered by the Chemisch-Pharmazeutische A.-G., Bad Homburg, Germany, "for the painless parenteral quinine-therapy in inflammatory affections of the lower air passages." The Council found the preparation unacceptable and submitted its findings to the German firm. The firm adopted the name Quicamphol for the preparation and took other measures in an effort to make the product acceptable. Quicamphol is now sold in the United States by Spicer and Company, which firm offers it "for intramuscular injection in bronchitis, pneumonia, and pulmonary infections generally." The Council declared Quicamphol (Transpulmin) unacceptable for New and Non-official Remedies because the claims for the value of the preparation in the treatment of lobar pneumonia, influenza, etc., are unsupported by satisfactory clinical evidence (Jour. A. M. A., November 9, 1929, p. 1471.)

President's Letter

THE organization of men into groups for their mutual protection or gain dates back into very ancient times. Organized activities have varied with changing conditions and advancing civilization but the underlying principles animating all social organizations have remained unchanged, because human nature remains basically the same today as it was in the beginning.

The congestion of peoples into great populations of both rural and urban types, the growth of industrialism, the expansion of knowledge, the figurative contraction of distances by virtue of our modern means of quick communication, have given rise to tremendous social problems which are challenging us for solution.

Society is striving to understand the conditions in which it finds itself, is courageously attempting to untangle the maze of conflicts, is seeking to find the way to establish social, industrial and economic justice. Manifestly society as a whole cannot act intelligently on each of the great multiplicity of problems to be considered, therefore quite naturally groups with common interests have formed themselves into organizations for the purpose of studying their own needs, their relations to other groups, their position in relation to society as a whole, the best means of serving themselves, each other and that which they themselves compose—the public.

Thus we have financial organizations, labor organizations, industrial and agricultural groups, social welfare, child welfare, lay health bodies and what not. It is small wonder that in the earnestness of their activities they cross paths or seem to, and often find themselves in conflict with each other.

The professional and scientific bodies have been the playthings of the other groups to a very considerable extent. This fact has touched the medical profession more directly, perhaps, than it has the others. The old austere spirit of professional aloofness has long held sway within our ranks. Even yet there are many of us who feel that it is beneath our dignity to enter into active solution of medical economic problems, except as individuals. However, the field men of medicine, they who are at the bedsides of the sick and injured, while accepting themselves as men of science, none the less realize that they earn their living by caring for the sick. Their professional spirit gives them primal interest in helping their patients. Their pecuniary interest is secondary. The professional spirit cries out for untrammeled scientific freedom. The spirit born of ancestral independence of action likewise cries for freedom. It instinctively rises rebelliously against economic thraldom.

Our purely scientific organizations found it necessary to add to their activities a phase which we are pleased to call medical economics. This field has broadened until we now find that the Minnesota State Medical Association has at least eleven committees engaged in studying our problems in relation to the public, to various technical services, to exogenous groups of healers, to the procedures of the Department of Public Health, to public health education and to other closely related matters.

The great swing and scope of education got under way while we slept, so to speak, or worshipped at the shrine of science, wholly unmindful of what was happening. Suddenly we began to realize that the medical profession was losing its one time position of honor and prestige. Because of our self centered and narrow attitude we were relinquishing our function as public educators and to just that extent failing in our professional duty. Whereas a generation ago the doctor worked as an individual, was professional advisor, political counsellor, general all around sage and burden bearer, now the scenes had changed and collectivism had come to be the mode of action. Soon we found an impatient public was carrying on its own system of health propaganda and education. Evidently if we were not going to do it the public would do it themselves, though not always to their best advantage but certainly to our disadvantage.

Then we woke up! The result has been one of splendid accomplishment. Today we have an aroused profession, aroused to its public responsibility, working organically as a unit. It is taking the lead as an organized body in all of the many movements in which medical lore can be of service. It no longer stands idly by while its larger work is being mismanaged by others. It is guiding, wisely directing, helping. It is thrusting aside the ill informed, less than half trained, self seeking group who had the pretensions to teach the laity. Such were accepted for a time on many occasions by lay organizations, but only because we ourselves were not available.

Organization has redeemed our honor. We should rejoice. But organization and the work it entails which devolves upon us is costly. That is why state society dues have been raised. That is why, having placed our shoulders to the wheel, we must keep them there, lest we step back into the quagmire of dishonor.

S. H. Boyer

President,
Minnesota State Medical Association.

POISONING FROM CINCHOPHEN

When cinchophen was first introduced to the medical profession in 1908, it was advocated as a specific analgesic in gout. For many years its use was restricted to gout and conditions thought to be of gouty origin. Gradually, as it became apparent that its power to relieve pain was not specific, it was prescribed in other conditions, and has been widely used in all sorts of painful affections, not only by the medical profession but by the public at large and even in proprietary and patent medicine mixtures.

Partly because of its restricted administration in the first decade of its use, it was considered to be relatively innocuous and safe when given in large doses over long periods of time. But in 1922, Schroeder reported seventeen cases in which various toxic manifestations had followed the ingestion of cinchophen. Since that time, many reports of toxic effects from cinchophen have appeared, with gradually increasing frequency. These effects have varied from urticaria, and toxic cutaneous rashes, to gastro-intestinal disturbances and serious hepatic toxemia, frequently terminating in yellow atrophy and death. In August, 1929, Reichle reviewed forty-seven case reports which had appeared in the literature. Eleven of the patients had died of toxic jaundice. At The Mayo Clinic, four patients who had taken cinchophen or derivatives of cinchophen at home have died from disorders definitely attributable to the drug; two others, with icterus of moderate severity, ultimately recovered after discontinuing the drug. Because of our experience with these cases, we now make careful inquiry concerning previous ingestion of drugs of all patients who present themselves with jaundice, especially in cases in which the jaundice is from intrahepatic causes. If this inquiry is always made the diagnosis of intoxication from cinchophen will be made more frequently. Since the pathologic picture in these cases differs in no way from that of the idiopathic form of acute yellow atrophy, in order to make the diagnosis it is necessary to correlate the pathologic data with the clinical history, especially as it pertains to previous medication.

Apparently it is not recognized generally that cinchophen is a dangerous remedy. In large part this may be due to the fact that most of the cases reported have been published in journals which do not have wide circulation in this country. That some of the manufacturers of the remedy appreciate its toxic potentialities is evident by the cautions which accompany packages of their preparation, advising that the drug be discontinued immediately if any gastro-intestinal symptoms occur. Unfortunately, however, after gastro-intestinal symptoms have manifested themselves, the injury has been done, and stopping the drug often is ineffective in checking the

progress of the toxemia. In fact the first symptoms have been known to appear even after the medication has been stopped.

There appears to be marked variation in individual susceptibility to cinchophen. One man seen at The Mayo Clinic had taken it almost daily for thirteen years without any ill effects, whereas in another patient pruritus developed after the first dose. The latter patient continued to take the drug and subsequently died of subacute yellow atrophy. In another instance the preparation was administered for more than six months before gradually developing jaundice appeared; the jaundice subsided after medication had been stopped.

It has been thought that impurities in the product might be responsible for the toxic properties rather than the drug itself. In the case of poisoning from cinchophen reported in this issue by Stacy and Vanzant, the preparation used was of the highest quality. A conjecture also has been advanced that those people who are sensitive to cinchophen break down the molecule in some abnormal way, producing toxic products. This has not been proved but the subject is being investigated under a grant from the American Medical Association at the present time.

Cinchophen often has been administered interchangeably with the salicylates, but by the use of cinchophen the patients are unnecessarily subjected to risk. As this becomes better known among the members of the profession, undoubtedly cinchophen will be prescribed less; other and safer analgesic drugs will be given preference. Meanwhile, however, pharmacists will continue to sell directly to the public countless packages of a dangerous drug, and patent medicines containing this drug still will be compounded. This uncontrolled sale should be regulated either by legislation, or by publicity, or by both.

YALE'S INSTITUTE OF HUMAN RELATIONS

The mere announcement that Yale University is establishing an Institute of Human Relations sounds as fantastic and presumptuous as the proposal of H. G. Wells to write a History of the World. And yet Mr. Wells did it and it looks as though the few remaining millions necessary to round out the building and endowment program of the so-called Human Welfare Group will be forthcoming. This group will consist of the Yale Medical School, the Yale School of Nursing, the New Haven General Hospital and Dispensary, and this so-called Institute of Human Relations, the whole representing an investment of some thirty-five million dollars.

This old world is not doing as well as it should. Phenomenal progress has been made in recent years along material lines. Science has done wonders through inventions which have substituted the machine for man power, has greatly speeded up transportation by land, sea and air and has made the individual a world citizen through inventions which have facilitated world-wide communication. And yet there is serious question whether the human being is any nearer the goal of real happiness than he was before all this scientific and material progress was achieved. Medical science has lengthened life expectancy and has reduced the prevalence of disease as a whole, but that remnant of barbarism—war—has not been outlawed. Suicide is on the increase. Poverty and unemployment in spite of great national wealth is still with us. Law violation has shown a tremendous increase in recent years. Hospitals for the insane and institutions for the feeble minded are full to overflowing.

Many agencies, religious, moral, social, governmental, medical, etc., are working along their respective lines in an effort to better human conditions. But there has been a surprising lack of correlation of these various activities. This correlation is what the Institute of Human Relations is going to attempt. The Institute in addition to being closely associated with the medical activities of Yale University will also be affiliated with the divinity and law

schools, and the departments of psychology and sociology. Thus all university activities which have to do with man's mental, physical and social welfare will be brought together to some extent under the one roof of the Institute. Research will be an important part of the Institute's work. Members of the graduate schools of medicine, law and divinity will also have the benefit of instruction in other matters bearing on human welfare than their own.

There are certain subjects which might well be added or substituted if need be in undergraduate medical instruction of today, to advantage. As a result of present-day medical training it is only too easy for the young physician to see only the physical side of the patient and to forget that his mental attitude, family and financial worries may play an important part in his complaint. We can see a distinct advantage in undergraduate instruction in psychology and sociology in furnishing the young physician of today with that something so valuable in the handling of patients which the family doctor of yesterday possessed in such large measure.

Such a praiseworthy attempt to evolve some solution for some of the tremendous social problems of today merits the support of serious minded capitalists. That the Institute of Human Relations has obtained the generous support of such individuals as well as grants from the Rockefeller Foundation, the General Education Board and the Commonwealth Fund, is evidence of the sense of custodianship alive in at least some of our wealthy citizens. The results of this undertaking which seems almost in the nature of an experiment, will be awaited with considerable interest by medical men especially.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

STATE OF MINNESOTA VS. BOYD T. WILLIAMS

Above defendant, who has been conducting a cancer sanatorium in Minneapolis, and who was convicted by a jury of practicing healing without a basic science certificate, paid a fine of $250.00 to the Clerk of the District Court of Hennepin County on Monday, March 24, 1930. Following the defendant's conviction, a stay of execution of sentence was granted to enable Williams to appeal his case to the Supreme Court. However, the plans for perfecting the appeal were abandoned upon the payment of the fine.

COMMUNICATION

AMERICAN MEDICAL ASSOCIATION

October 25, 1929.

Dr. E. A. Meyerding, Secretary,
Minnesota State Medical Association,
11 W. Summit Ave.,
St. Paul, Minnesota.

Dear Dr. Meyerding:

Your letter of October 22, regarding the Midwest Company, has been referred to me.

The Midwest Company is a trade style used by Mr. James C. Fifield and his wife, in partnership. It is the intention of Mr. Fifield to get up a so-called biographical directory of American physicians and surgeons, comparable in its field to the book that Mr. Fifield issues—"The American Bar"—having a legal field.

"The American Bar" is a reputable publication that is held in fairly high esteem by men in the legal profession. The book comprises brief biographical sketches of various members of the American bar, the sketches being even less detailed than those that appear in "Who's Who." So far as we have been able to learn, there is no commercial taint to this book. The book itself, we might state, sells for $30.00 a volume.

Mr. Fifield seems to be thoroughly reliable and honest and gives every evidence of wanting to make his proposed "American Physicians and Surgeons" just as reliable a publication as "The American Bar."

The method to be used by Mr. Fifield and his agents in determining the eligibility of individual physicians and surgeons for inclusion in his proposed book is that of taking the names of Fellows of the American Medical Association, of the American College of Surgeons and of the American College of Physicians, and have his representatives call on them. We understand that each physician called on has submitted to him a certain number of names of the other eligible group in the same locality, and the physician is asked whether, in his opinion, such men should be eligible to inclusion in the proposed book.

Mr. Fifield is also considering soliciting advertisements for the proposed directory. He tells us, in a letter received recently, written in answer to some specific questions we put to him on the point, that his plan is to confine his advertising to such advertisers as are accepted by the publications of the American Medical Association.

He tells us, further, that his representatives, who are calling on doctors, are at the same time attempting to secure orders for the book. As we see it, there can be no serious objection to this plan, provided, as we have said to Mr. Fifield, it is made quite plain to the physicians that a subscription is not, in any sense of the word, a *sine qua non* for eligibility to the book.

Very sincerely yours,

ARTHUR J. CRAMP.

A PAGE FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

That the medical profession is already in partnership with the profession of public health in the field of health education is clearly indicated in this interesting survey of the membership of the leading health and medical associations of the country and the programs of two of their recent biggest meetings. The survey was just completed by Dr. R. O. Beard for the information of the public health education committee of the Minnesota State Medical Association.

It shows that a large army of public health workers neither practice medicine nor hold an M.D. degree. Among them are public health teachers, sanitary engineers, sanitary chemists, psychologists, sociologists and public health nurses.

Such persons as these are sharing control of the profession of public health with the medical profession. Their qualifications for the work are as substantial and important, in the opinion of Dr. Beard himself, as those of the medical profession, many of whom are not, themselves, qualified for public health work.

At any rate, it is entirely fitting, in his opinion, that both should grow together side by side, sharing equally in the great cause of health education for the public at large.

Dr. Beard's report follows:

RESULTS OF STUDY OF HEALTH AND MEDICAL ASSOCIATIONS

The Membership of The American Public Health Association of 1929 consists of:

(a) Those who by education, experience, interest and appointment are exclusively engaged in public health work, and who do not hold the Degree of M.D., in the proportion of ..... 52 per cent

(b) Those who hold the Degree of M.D., but are exclusively engaged in public health work, in the proportion of ..... 18 per cent

(c) Those who hold the Degree of M.D., and who are practitioners of medicine, but are interested in, and more or less employed in, public health service to the proportion of ..... 30 per cent

Total ..... 100 per cent

The membership of the American Child Health Association of 1929 consists of:

(a) Those who by education, experience, interest and appointment are exclusively engaged in public health work, and who do not hold the Degree of M.D., in the proportion of ..... 58 per cent

(b) Those who hold the Degree of M.D., but are exlusively engaged in public health work, in the proportion of ..... 24 per cent

(c) Those who hold the Degree of M.D., and are practitioners of medicine, but are interested in, and more or less employed in, public health service in the proportion of ..... 18 per cent

Total ..... 100 per cent

The 1929 program of the American Public Health Association and related public health organizations, meeting in Minneapolis, offered addresses, articles or papers to the number of 185

Of these, the number contributed by public health workers, without medical degrees, was ..... 132, or 71.3%

The number contributed by writers holding the Degree of M.D., but engaged exclusively in public health work, was ..... 33, or 17.9%

The number contributed by writers holding the Degree of M.D., which were of combined medical and public health interest was ..... 20, or 10.8%

The 1928 program of the American Medical Association, meeting in Minneapolis, offered addresses, articles or papers to the number of 296

Of these, the number contributed by practitioners of medicine and bearing upon the causes, diagnosis or treatment of disease were ..... 261, or 88 %

While the number contributed by Doctors of Medicine and devoted to the discussion of topics related to preventive medicine, public health, and public health education were ..... 25, or 12 %

The 1930 program of the American College of Physicians, meeting in Minneapolis, offered addresses, articles or papers to the number of 245

Of these, the number contributed by practitioners of medicine, and bearing upon the causes, diagnosis or treatment of disease was ..... 231, or 94 %

While the number contributed by Doctors of Medicine and devoted to the discussion of topics related to preventive medicine, public health or public health education were ..... 15, or 6 %

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 10:15 o'clock every Wednesday morning over Station WCCO, Minneapolis and St. Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of May will be as follows:

May 7—Your Hospital
May 14—Blue Ribbon Children
May 21—Cirrhosis of the Liver
May 28—Cause of Headache

MINNESOTA RADIOLOGICAL SOCIETY

The Minnesota Radiological Society, a new organization for the study and advancement of radiology, held its first formal meeting at the Mayo Clinic, Rochester, Minnesota, on March 1, 1930. The following program, prepared by Dr. B. R. Kirklin, was presented.

1. "Roentgenologic Manifestations of Malignant Disease in the Colon," Dr. H. M. Weber.
2. "Gastro-Jejunal Ulcer," Dr. J. D. Camp.
3. "X-ray Studies on Tuberculous Spine and Shoulder in Children," Dr. R. K. Ghormley.
4. "Mediastinal Empyema," Dr. Jacob Sagel.
5. "Roentgen Diagnosis of Small Pleural Effusions," L. G. Rigler.
6. "Specific Radio Sensitiveness of Cells and its Significance to Radio Therapy," Dr. A. U. Desjardins.
7. "A Radium Technique in the Treatment of Carcinoma of the Cervix Uteri," Dr. R. E. Fricke.
8. "Results Obtained from Irradiation Therapy in Cases of Carcinoma of the Cervix Uteri," Dr. H. H. Bowing.

A banquet was held that evening at which the following addresses were given:

"Use of Iodized Oil in Gynecological Diagnosis," Dr. L. M. Randall.

"Preliminary Report of Intravenous Urography by Means of Uroselektan," Dr. C. G. Sutherland and Dr. W. F. Braasch.

The next meeting will be held in Duluth, Minnesota, in connection with the meeting of the Minnesota State Medical Association, in July.

KIDNEY SYMPOSIUM

A symposium on the kidney in health and disease will be held at the University Medical School, Minneapolis, July 7 to 18, 1930. Various phases of a limited part of the field of internal medicine will be presented by a number of physicians whose names are familiar to medical men both in this country and abroad.

Physicians are invited to attend the meeting, registration for which will take place at 9 A. M., Monday, July 7, at the Eustis entrance of the University Hospital. There will be no registration fee. Registration may be made in advance to Dr. Hilding Berglund, University Hospital, Minneapolis. Dormitory accommodations will be available to those who register before June 1.

The program includes the following:

Dr. A. J. Carlson, University of Chicago
Dr. G. Carl Huber, University of Michigan
Dr. E. K. Marshall, Johns Hopkins Medical School
Dr. R. E. Scammon, University of Minnesota
Dr. C. M. Jackson, University of Minnesota
Prof. F. Volhard, Frankfort-on-the-Main
Dr. A. N. Richards, University of Pennsylvania
Dr. E. T. Bell, University of Minnesota
Dr. R. N. Bieter, University of Minnesota
Dr. H. L. White, Washington University, St. Louis
Dr. W. F. Longcope, Johns Hopkins Hospital
Dr. Paul B. Rehberg, University of Copenhagen
Dr. L. G. Rowntree, Rochester, Minnesota
Dr. H. Berglund, Rochester, Minnesota
Dr. A. D. Hirschfelder, Rochester, Minnesota
Dr. L. Leiter, University of Chicago
Dr. R. A. Gortner, University of Minnesota
Dr. Harold Diehl, University of Minnesota
Dr. McN. Wetherby, University of Minnesota
Dr. H. P. Wagener, Rochester, Minnesota
Dr. G. E. Fahr, University of Minnesota
Dr. N. M. Keith, Rochester, Minnesota

The program will consist of morning and afternoon sessions.

MINNESOTA SOCIETY OF INTERNAL MEDICINE

The next meeting of the Society of Internal Medicine will be held at Duluth, Monday, May 26, 1930.

MINNESOTA STATE MEDICAL ASSOCIATION

The annual meeting of the Minnesota State Medical Association will be held in Duluth, July 14, 15 and 16, 1930.

Addresses will be given by the following:

Dr. Karl Meyer, Associate Professor of Surgery, Northwestern University
Dr. Ludwig Hektoen, Chicago
Dr. W. J. Mayo, Rochester
Dr. Ralph Kinsella, Professor of Internal Medicine, St. Louis University
Dr. E. C. Davidson, Detroit
Dr. R. S. Dixon, Detroit

Symposia on Traumatic Surgery, Carcinoma, Rheumatic Fever, Anesthesia, Therapy, and Our State Institutions, have been arranged.

Dr. Olin West, secretary of the American Medical Association, J. G. Crownhart, secretary of the Wisconsin State Medical Association, and W. J. Burns, secretary of the Wayne County Medical Society of Detroit, will speak at the Medical Economics meeting.

The Duluth profession is making extensive prepara-

tions for the meeting. All committees are appointed, President S. H. Boyer reports, and they are already working together under the general chairmanship of W. A. Coventry.

Following are other committee heads recently appointed: C. H. Scherer, banquet and entertainment; L. R. Gowan, civic clubs; E. Z. Shapiro, publicity; L. A. Barney, convention halls; J. F. Lepak, exhibits; C. L. Haney, reception; Gordon McRae, reunions and luncheons; B. F. Davis, hotel accommodations, and R. A. Nelson, sports. F. H. Magney and P. F. Eckman are vice-chairman and secretary, respectively, of the general committee.

One medical man remarked that he was attending the meeting for no other reason than to learn something about what his patients pay him for. He hoped other programs would imitate the state meeting and include more therapy for a change, he said.

Hotel reservations for members should be made through Dr. Ben F. Davis, 25 North Tenth Avenue East, Duluth, Minnesota.

AMERICAN COLLEGE OF PHYSICIANS

FIFTEENTH ANNUAL CLINICAL SESSION

The American College of Physicians will hold its Fifteenth Annual Clinical Session at Baltimore, Maryland, from March 23 to 27, inclusive, 1931. The Lord Baltimore Hotel will be headquarters.

Dr. Sydney R. Miller, Baltimore, as President, will have charge of the selection of the general scientific program. Dr. Maurice C. Pincoffs, of Baltimore, has been appointed by the Board of Regents as the General Chairman of the Session, and will make all local arrangements, including the making up of the program of clinics. Business details will be handled by the Executive Secretary, Mr. E. R. Loveland, from the College headquarters, 133-135 S. 36th Street, Philadelphia, Pa.

The attention of secretaries of various societies is called to the above dates, in the hope that their societies will select non-conflicting dates for their 1931 meetings.

STEARNS-BENTON COUNTY MEDICAL SOCIETY

The Stearns Benton County Medical Society met at St. Cloud, Minn., April 17, 1930.

The program consisted of the following papers: "Medical Economics," H. L. Gorneflo, St. Cloud; "Medical Legislation," Dr. Savage, St. Paul; "Public Health," Dr. G. Earl, St. Paul.

Motion that endorsement of present $15.00 state dues be continued was passed.

Election of officers resulted as follows: E. M. Kingsbury, Clearwater, President; H. B. Clarke, St. Cloud, Vice President; F. J. Schatz, St. Cloud, Treasurer; P. E. Stangl, St. Cloud, Secretary; R. N. Jones, St. Cloud, Censor; Delegate to State, C. B. Lewis, St. Cloud; Alternate, Geo. Sherwood, Kimball.

P. E. STANGL, *Secretary.*

WOMAN'S AUXILIARY
Minnesota State Medical Association

Minnesota County Medical Auxiliaries and Their Presidents

Blue Earth County—Mrs. A. A. Passer, Olivia, Minnesota.
Camp Release Co.—Mrs. J. S. Holbrook, 419 South Broad Street, Mankato, Minnesota.
Hennepin County—Mrs. James Blake, Hopkins, Minnesota.
McLeod County—Mrs. Thos. Trutna, Silver Lake, Minnesota.
Park Region—Mrs. W. W. Draught, Fergus Falls, Minnesota.
Ramsey County—Mrs. E. M. Hammes, 1456 Summit Avenue, St. Paul, Minnesota.
Red River Valley—Mrs. H. Froehlick, Thief River Falls, Minnesota.
Rice County—Mrs. Joseph Moses, Northfield, Minnesota.
Stearns-Benton—Mrs. W. B. Richards, St. Cloud, Minnesota.
St. Louis County—Mrs. F. W. Spicer, 1631 East Fifth Street, Duluth, Minnesota.
Washington—Mrs. O. B. Freligh, Stillwater, Minnesota
West Central—Mrs. C. Frank Ewing, Wheaton, Minnesota
Wright County—Mrs. G. H. Norris, Annandale, Minnesota
State President—Mrs. J. D. Lyon, 3617 Pleasant Avenue, Minneapolis, Minnesota.

The word "auxiliary" is defined by the Standard Dictionary as "giving or furnishing aid or support, especially in a subordinate or secondary manner—supplementary—accessory." I take the liberty of presenting this definition because it so well expresses the real objects and purposes of any Auxiliary to any Medical Society, and at the same time so definitely states the limitations, about which I believe there should be a clear understanding, to avoid future trouble.

Joining and taking an active part in the Woman's Auxiliary could very well be ranked as the first activity which any physician's wife should assume outside her home. The immediate welfare of physicians and their families and the future of medical practice depend upon what the public thinks and does with regard to medical practice and health activities. Organized medicine exists largely for the scientific advancement of its members, the betterment of the profession, and proper guidance of health activities. Except for scientific education, practically every purpose of organized medicine can be as well, or better, accomplished by a woman's auxiliary than by a medical society itself. Some of these activities are: The promotion of friendliness, the guidance of health activities, and health education.

It is generally true that physicians' wives are, or can easily become, active in the public health pro-

grams of the various lay organizations whose work is everywhere impinging upon medical practice. These lay health organizations accomplish great good both for the public and the profession, and auxiliary members can very easily see to it that the various lay activities with which they are connected are conducted in a way that meets with the approval of the physicians in their county. In this way a possible liability can easily be turned into a tremendous asset.

One of the favorite forms by which quackery propagates itself is through lectures offered to women's clubs and other lay organizations. The State Medical Society has a speakers' bureau which can send qualified physician speakers to any or all lay meetings. The members of the Woman's Auxiliary could very easily eliminate faddists as club speakers and also find dates for members of the state society speakers' bureau. Lay education of this sort will destroy the cults faster than any laws.

Scientific medicine needs the coöperative aid which can come through such auxiliaries. Whatever makes for better understanding between physicians and their families makes for better organizations. Nowadays women's clubs exercise a strong influence on civic affairs. A state woman's auxiliary of the Minnesota Medical Association, composed of component county woman's auxiliaries, can become a real factor in promoting public health work.

A perusal of the rules laid down by the Auxiliary to A. M. A. and to the State of Minnesota will show that the interests of the profession and of the lay public have been constantly kept in mind. A county woman's auxiliary, working along legitimate lines, can be of real aid and service, both to the profession and to the laity. The members of such an auxiliary can maintain contacts and promote interests and activities vitally concerned with the public health, and can do work for which busy physicians only rarely can spare the time.

MISCELLANEOUS

THE PRACTITIONER AND THE MEDICAL SOCIETY LIBRARY

There should be little need of speaking to physicians about the importance of a medical library. The priest physicians and astrologers and later the physicians and alchemists preserved the records of science while priests and monks preserved literary and religious records. The tradition has persisted. In many numerous visits to physicians' offices, I can recall none where there was not somewhere in sight at least a bookcase or a shelf in which there was not—also "at least"—the residual text-books used in the practitioner's medical school course, a pamphlet or two attesting attendance at medical conventions and a more or less aging pile of the Journal of the American Medical Association or some similar professional periodical.

In times not very remote the physician's library was somewhat indicative of his professional status. Not infrequently it was an asset to his estate or passed on to his successor in practice. For a long while medical theory and practice were fairly stationary. Really revolutionary literature appeared at sufficiently lengthy intervals to make it possible to keep such a collection fairly well up to date even though cupping and leeching ceased to be common, and jalap, blue mass and calomel successively lost their prestige.

In latter days, the private medical library is not keeping pace with the mechanical equipment and artistic, decorative appeal of medical offices. The reason is not far to seek. It would be carrying coals to Newcastle to speak even briefly of the manifold changes in theory, technic and practice in the profession. In fact, most physicians would consider it presumptuous for a layman to do so. The auxiliary sciences which contribute to the number and rapidity of these changes are many. They range from photography to glassmaking, from chemistry to papermaking. It is said that five hundred current periodicals of medical emphasis would be needed to make any medical library really first-class and perhaps two or three times as many more to make it approximately complete. Monographs and text-books are increasing at a similar rate. All of these are expensive to produce and the publishers do not list them at below cost prices. If the reports of the average income of physicians are correct, there are very few communities in which many practitioners could approximately keep up to date even in a special field. Moreover, the shelf room required to house the additions would soon tax the capacity of any private office. It is this relation to other library fields which gives a mere layman his excuse for speaking of medical libraries.

To meet these rapid changes, physicians seem to have developed several methods. All involve coöperation, whether the method selected is attendance at special short courses connected with hospital or medical school; attendance at even shorter courses in the form of professional conventions; formation of group clinics; or by the formation of clinic or medical society libraries. No surgeon, however skillful, even considers the acquisition of complete surgical equipment. Instead of adopting the plumbers' method of going back for tools after looking over the job, he and his patient, after the preliminary diagnosis, go to the hospital, or clinic, where combined resources have provided equipment and environment beyond the possibility of individual purses. Instead of stocking his back office with cabinets filled with jars of tablets or pint bottles of suitably colored and flavored liquids, he writes prescriptions which only the well-stocked pharmacy can be expected to fill.

Recognition of a similar need of coöperation in medical literature has fostered the foundation of medical libraries for common use wherever there is a fair-sized group of physicians, be they specialists or general practitioners. Nevertheless, it may be questioned whether medical libraries are used to more than a fraction of their potential value. Too often their care and organization are left to the leisure time of skilled phy-

(Continued on Page 340)

CONSULTATION BUREAU

Wm. A. O'Brien, M.D., *Director*
Minnesota State Medical Association
11 West Summit Avenue
Saint Paul, Minnesota

1. *Question.*—I have a young man who states that he wore a condom during sexual intercourse several weeks ago. About three weeks after exposure he noticed a sore on the penis. It gradually enlarged to the size of a ten cent piece, and was oval shaped. At present it is indurated but not painful. The right inguinal glands are enlarged and slightly tender. The left inguinal glands show slight enlargement but are not painful. I suspect that the lesion is a primary syphilitic affair. I wish to start treatment early if it is syphilitic and would like your advice as to the best way of making an early diagnosis.

   Answer.—An early diagnosis of syphilis may be made by examining material from the ulcer for spirochetes. This may be done by a dark field examination. In addition, it is advisable to take a blood Wassermann. Although the blood Wassermann is not positive in from thirty-five to forty-two days after infection, spirochetes may be found from fifteen to eighteen days after inoculation. It is necessary to have your microscope and field ready for this examination, as it cannot be sent a distance to have it done. Unless you care to wait for the blood to become positive, it would be advisable for you to have the examination done elsewhere if you are not accustomed to doing these examinations yourself.

2. *Question.*—I wonder if you could give me information about a new drug called "Tethralin," which is said to be used with success in the treatment of trigeminal neuralgia.

   Answer.—"Tethralin" (trichlorethylene) is the drug you have in mind. It was discovered accidentally that this drug had an effect on the trigeminal nerve of workers in a factory where it was used. It was thought from this observation that perhaps there was some specific effect on the trigeminal nerve, and it was therefore tried in cases of neuralgia. About twenty drops are placed on cotton and sent into the nose during an attack. Approximately half the people using the treatment reported it successful. It is worthy of trial and should be used as indicated above.

3. *Question.*—I have a young girl, eighteen years old, who has had psoriasis for the past year. I have tried thyroid extract, Fowler's solution, salicylates, and milk injections without getting any favorable results.

   Answer.—It must be kept in mind that psoriasis is a chronic, recurring disease. Therefore, no treatment that might cause serious consequences should be used unless one has had a large experience in treatment of the same. Under this heading would be included such drugs as arsenic and other agents which might of themselves give trouble. The following is recommended: (1) Have the patient anoint the body with liquid tar soap and follow with a warm bath. (2) Use ammoniated mercury ointment locally for the lesions which are most troublesome. (3) Attempt to change the patient's attitude toward the disease. Try to get her to see that psoriasis will probably be with her the rest of her days, and she should not be seeking a cure in vain, but rather relief of symptoms. Dermatologists of large experience find that this is very helpful in bringing not only physical but also mental relief to the sufferers from this disease.

4. *Question.*—I have a single female patient, age eighteen, who has been having great trouble with dysmenorrhea, requiring injections of morphine at the beginning of each menstrual period, for the past two years. Her menses began at twelve years of age and are of the regular, four week interval type. They used to last two days, but now last three days. The pain comes on at the same time as the flow and is severe and cramplike over the lower abdomen. It lasts about twenty-four hours, and is usually accompanied by vomiting. She passes no clots, but has a slight leukorrhea, lasting two or three days after menstruation. In December, 1929, she was given a general anesthetic, and dilation and curettage done, followed by the insertion of a glass stem pessary, which was left in five weeks. Bimanual examination at that time revealed no disease of the uterus or adnexa, and the uterus was normal in position. Following the use of a pessary, she had relief, but her trouble has recurred since the pessary was removed, but this does not seem to afford any relief. She has had no serious illness or injury, and her mother states that she herself never had any serious menstrual disturbance. Please advise further therapy.

   Answer.—The following suggestions have been received for the treatment of your patient: (1) Physical exercise. Many young girls who come to training schools in hospitals with dysmenorrhea seem to respond very well to physical activity. Gymnasium work is often prescribed for patients of this type, especially if they are lethargic and underdeveloped and undernourished. (2) Displacement. You have already stated that there is no displacement of the uterus, so that correction is not indicated. (3) Attempt to determine if the dysmenorrhea is of the spasmodic type. It is necessary to test the type of dysmenorrhea by giving atropine in good sized doses. Several fairly large doses should be given at the onset of menstruation; and if the pain is of the spasmodic type, it will probably give relief. (4) Benzyl succinate is commonly used. This is a soluble preparation and may be given in water, five grains every half hour up to twenty-five grains. It should be started as soon as the patient believes that she is going to menstruate. (5) Hot douches, hot sitz baths, and applications of heat are often helpful. (6) Psychic factors. This is often present, and an attempt should be made to correct the patient's attitude toward her complaint.

OF GENERAL INTEREST

Dr. Hilding C. Anderson of Duluth has announced the changing of his name to Anderson C. Hilding.

The death of John Bessesen, father of Dr. William A. Bessesen of Minneapolis, occurred in March, 1930.

Mrs. Knut Haegh, wife of Dr. Knut Haegh whose death occurred in 1925, died at her home in Minneapolis, in March.

Dr. C. B. Wright is to speak before the Georgia Medical Society at their annual meeting at Augusta on May 14. He is also to address a public health meeting.

Dr. E. E. Zemke, who has finished his hospital year in St. Mary's Hospital, Duluth, will locate in Fairmont, where he will be associated with Drs. F. N. and R. C. Hunt.

Col. Kent Nelson, director of the University of Minnesota medical unit of the reserve officers' training corps, will leave the university at the end of the school year, it has been announced.

Dr. Phoebe Pearsall-Block, who returned to Moline, Illinois, last July after five years' residence in Virginia, Minnesota, was elected president of the Moline Physicians' Club at the annual meeting held March 7, 1930.

Drs. F. H. Stangl, P. E. Stangl, C. B. Lewis and W. L. Freeman, who have been practicing under the names of Drs. F. H. and P. E. Stangl and Lewis Clinic at St. Cloud, Minnesota, joined their resources April 7, 1930, and will practice in the future under the name of Lewis-Stangl Clinic, at 101 Seventh Avenue South, St. Cloud, Minnesota.

Max Mason, Ph.D., formerly president of the University of Chicago, was elected president of the Rockefeller Foundation, to succeed George E. Vincent, Ph.D., who retired January 1, 1930. Dr. Mason was assistant professor of mathematics at Yale from 1904 to 1908 and professor of mathematical physics at the University of Wisconsin from 1908 to 1925.

Phyllis Jeannette Kay of Little Falls, Minnesota, has been selected as the state winner in the second annual Gorgas Memorial Essay Contest. The subject this year was "The Gorgas Memorial, Its Relation to Personal Health and the Periodic Health Examination" and the national winner to be chosen in May from the selected winners in each state will receive the $500 cash prize offered by Mr. Charles R. Walgreen, of Chicago, of drug store fame.

After nine years of preliminary effort a Royal College of Physicians and Surgeons of Canada was established last November 20th. By an act of Parliament one hundred and forty-four professors of medicine, surgery, gynecology and obstetrics at the University of Toronto, McGill University, Laval University, the University of Montreal, the University of Manitoba, and the University of Alberta, were made charter members of the organization.

The American Hospital Association has designated May 12 as National Hospital Day. This particular day was chosen because it is the birthday of Florence Nightingale, who is rightly credited with having done so much for the nursing profession and also in raising the standard of hospital service. The public is being urged to pay a visit to a hospital on this date to become better acquainted with the nature of the service the hospitals are providing.

Minnesota's birth rate for 1929 was the lowest in the history of the state, according to a recent report of the vital statistics division of the state board of health.

During the year there were 46,502 births, a rate of 17.08 per 1,000. Since 1915, when the rate was 24.6 per 1,000 persons, there has been a steady decline in the birth rate. The statistics showed that the greatest number of births occurred during March, with 4,298. The death rate for the year also was one of the lowest on record, totaling 25,677, or 9.4 per 1,000 persons. Only in 1927, when the rate was 9.2 per 1,000, has the figure been bettered.

State Association News

The series of Colloquium lectures offered by the Committee on Hospital and Medical Education is proving decidedly popular this year. Willmar, Brainerd and Winona booked the course within 48 hours. Faribault, Litchfield and Owatonna made immediate inquiries.

Only five courses are to be given this spring, though more will be offered in the fall if possible, the committee announces. At least twenty medical men are asked to enroll for each.

The course includes eight programs spread over a period of eight weeks. Tuberculosis, cancer, obstetrics, hospitals, heart disease, immunology and public health are among the subjects scheduled for lecture and demonstration. The committee is to be congratulated on having secured five of these events without cost to those who book them.

President S. H. Boyer, E. A. Meyerding, Herman Johnson, and C. B. Wright, executive officers of the state association, will go to Marshalltown, Iowa, to address the annual meeting of the Iowa State Medical Association, May 14. On the way they will attend a special meeting of the Mower County Medical Society to be held at Austin, May 13.

N. O. Pearce, Minneapolis, addressed the Rice County Medical Society at Faribault, April 23, on "Pediatrics."

Bulletins were sent by the Educational Committee of the state association to Minnesota newspapers during the past month on the following subjects: "Heart," "Carbuncle," "Arthritis," "Eyestrain and the Movies," and "Tuberculosis." The last was designed to coincide and coöperate with the regular April diagnosis campaign carried on by the National Tuberculosis and the Minnesota Public Health Associations.

George Earl, chairman of the Committee on Public Health Education, spoke before the St. Cloud Stearns-Benton County Medical Society at St. Cloud, April 17.

There is no statutory provision in the laws of Minnesota compelling a physician or hospital to keep *x*-ray films for any definite length of time. Such is the finding of F. Manley Brist, attorney for the State Board

of Medical Examiners, who has made an exhaustive search of the laws of the state following a discussion of the matter at the Secretaries' Conference in St. Paul.

It is Mr. Brist's opinion, however, expressed in a letter on the subject received at state association headquarters, that all films, plates and like records be kept for a period of two years, at least, from the date of the work.

In the Minnesota statutes of 1927 covering malpractice suits, such suits must be commenced within two years, Mr. Brist points out, with this exception—that the statute does not exclude suits by persons under 21 years of age even after the two-year limit, until such persons have attained their majority.

Dr. F. E. Harrington, Commissioner of Health of Minneapolis, is directing the third annual campaign for the prevention of tuberculosis in Hennepin County. Nationally observed by tuberculosis associations throughout the country during the month of April, the local program of education in the prevention of the white plague will take place April 21 to May 1. Because of his connection with Lymanhurst, America's first school of its kind for tuberculous children, and his activity on committees of the National Tuberculosis Association, Dr. Harrington is especially qualified for leadership in the campaign which will reach into every home in the county, focusing public attention on the importance of early diagnosis of the childhood type of tuberculosis.

THE PRACTITIONER AND THE MEDICAL SOCIETY LIBRARY

(Continued from Page 337)

sicians who have little leisure time. Much routine work, which could be done better by some one specially trained to do it, is undertaken by physicians who know little about it. In too many cases, physicians who would not think of compounding prescriptions or of repairing their surgical instruments, load themselves with business details of book ordering, bibliography, abstracting and the like, which a good librarian could do as well or better in much less time and at less expense. This is true in even greater measure of the individual library work of the physician. His time can be saved in large measure by a good medical librarian. If she cannot do it, either she is not a good librarian or the work requested involves difficulties not previously suspected or anticipated. Exploration is often as necessary in medical work as in surgery and it sometimes reveals as unexpected complications.

The medical society library increases the possibility of securing the latest information on any medical subject because it represents or should represent the varied interests of the society it serves. Modern diagnosis is considered more accurate because it represents the combined or compromise opinions of several qualified experts, each looking at many of the same phenomena from different angles and discovering new symptoms. It is logical to expect also that the reports of study in different fields, of conditions much the same but with differing relations, should lead to more exact appraisal of phenomena in any or all of these fields. In other words, really significant data are much less likely to be overlooked by the many than by the individual.

The probability that really worthwhile material on the subject in question will be available is greatly increased when such material is selected by a variety of experts and, when acquired for the library, subjected to criticism by the other experts who use it. Every one using the library may partake of the advantages arising from such critical appraisal. He is in consultation, through the books and periodicals, with his colleagues who have already consulted them.

In many cases, the medical society library of moderate size is of greater direct value in practice than the larger medical school or great metropolitan society library which is used also for purposes of research. It must be selected with more discrimination because there is less money behind it. Practice must depend on research, but practice is not primarily research. The obscure symptom may often be interpreted only by a post-mortem and a series of later laboratory tests. This truth does not overcome the natural objection of most patients to advance science by personally furnishing post-mortem material. The reputation of the university professor may properly be based on lengthy laboratory studies and protracted analysis, but the professional and financial success of the practicing specialist is not based on similar methods. He seldom has time for lengthy study on a serious case. He must and does study the result of others' work as they report it.

The monograph which codifies the best average practice is often more serviceable to him than the promising but inconclusive experiment which he uses mostly when favorable conditions permit experiment or when desperate conditions suggest it as a last resort. The medical periodicals which the medical society library takes and keeps should also be chiefly those which stress the applications of medical theory or biological research. The practitioner, therefore, will often find in his own society library a collection of greatest value.

In communities like Minneapolis and St. Paul, there is a very definite place for the medical society library. It supplements the personal office library and reduces the necessary expenditure for it. In most cases, the society library will be adequate for the immediate needs of average practice. Where it is not, or where the specialist desires to pursue his research further, the large and rapidly growing biological-medical collection of the University of Minnesota is at his service, for almost unrestricted reference use within the library building. Private office, medical consultation and clinic or hospital (or both) are successive stages in medical efficiency. Private office reference collection, medical society library and large medical school or university reference library should be no less recognized as similar opportunities for medical and surgical effectiveness.—Frank K. Walter in Bulletin, Hennepin County Medical Society, Vol. 1, No. 5.

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of March 12, 1930

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, March 12, 1930. Dinner was served at 7 P. M. and the meeting was called to order at 8 P. M. by the President, Dr. Emil S. Geist. There were 50 members and 1 guest present.

Minutes of the February meeting were read and approved.

The Secretary read the report of the Executive Committee meeting held earlier in the evening. This was approved.

The scientific program of the evening consisted of a paper and two theses, as follows:

DR. WILLIAM F. BRAASCH (Rochester) read a paper on "Congenital Failure of Renal Rotation and Associated Anomalies" and showed numerous lantern slides of these anomalies.

DISCUSSION

DR. CAMPBELL BEGG (Wellington, N. Z.) (by invitation): Mr. President and Members of the Minnesota Academy of Medicine: I have to thank you very much for your welcome this evening. I feel it a great privilege that, thanks to the courtesy of Dr. Braasch, I am able to be present at one of your meetings. St. Paul and Minneapolis are well known to me through the preëminent men they have produced in various spheres of medicine. I also appreciated very much Dr. Braasch's masterly presentation of this subject. When pyelography is mentioned throughout the world, his name is certainly the one uppermost in all minds as the one who established the procedure on a practical basis.

The discussion of such a paper on short notice is not easy. The subject is most important from the point of view of the general surgeon as well as the urologist. Some of the bizarre shadows shown tonight are reminiscent of a zoölogical garden. The figures of many familiar animals can be seen in these shadows. I always picture the pyelogram of the non-rotated pelvis by comparing with a kangaroo. It can appropriately be called the "kangaroo" pelvis, the tail being the ureter. To work out theories of the formation of the anomalies of the urinary tract on the accepted developmental facts is rather an interesting pursuit, but when we find the axioms wrong the whole ingenious theory is apt to crumble. I remember in a paper working out the method by which aberrant ureters are produced by the assumption of the usual idea that the ureter comes as a bud of the Wolffian duct which forms the trigone and posterior urethra. Unfortunately and much to my annoyance, I read an article last year by a German writer contending that the Wolffian duct did not do this at all!

It is very difficult to analyze the factors that make the kidneys in their ascent adopt one position or the other. We might assume the slope of the psoas muscles as one of the factors of rotation, but when Dr. Braasch has shown that many of these non-rotated organs still retain fetal lobulation, it almost makes one think that a definite urge is present in the kidney itself. Immaturity in constitution leads to abnormality in position.

I see, however, no reason why kidneys retained in the pelvis should not come to lie on their side. The room in the pelvis is needed for other purposes and the kidneys are pushed by pressure into the position where they will take up least room, *i.e.*, on their sides—sometimes on one, sometimes on the other.

There is a type of fully-developed kidney which appears normal in the pyelogram and in which the pelvis lies in front of the vessels. This, incidentally, is one of the criteria by which to decide whether the displacement is by acquired torsion or is congenital. In torsion the relation of the vessels to the pelvis remains normal. Many years ago Dr. Charles Mayo advocated exposing the kidney pelvis from behind to remove a stone from it, and then to cut boldly down on the stone through the fat and other tissues without dissecting out the pelvic wall. The idea was to prevent fistula. Once when about to carry out this technic, I looked more closely at the structures and found that the pelvis was in front of the vessels, so that a bold incision from behind would have traversed the renal vessels before reaching the stone.

Abnormal renal arteries are the rule rather than the exception. On one occasion I encountered a pyelectasis caused, or at least accentuated, by an aberrant renal artery which was almost the sole supply of the kidney. It entered the lower pole. As I could not cut the artery without destroying the kidney, I cut the dilated pelvis right across the ureter and the lower section of the pelvis below the artery and brought it up on the other side. The result seemed to be satisfactory.

I should like again to say how great a pleasure it has been to be here tonight, to have heard such an excellent paper, and to have had the opportunity of meeting you all.

DR. F. E. B. FOLEY (St. Paul): I have been delighted with Dr. Braasch's presentation, and greatly instructed, but simply astounded by the amount of his material shown in the lantern slides. Such an array of anomalies is remarkable.

The importance of anomalies of the upper urinary tract as a subject of clinical urology is not generally appreciated. On a summary analysis of our own material it is found that, if cleavage anomalies (duplications) are included, these conditions are even more frequent than renal tuberculosis.

A good grounding in the pathology of urinary tract disease, of course, is essential in clinical urology. Knowledge of upper urinary tract embryology is likewise essential in clinical problems in which renal anomaly is concerned. That such anomalies are so frequent emphasizes the importance of at least a working knowledge of this embryology. If one is to have much to do with diagnostic and surgical urology, this is of great importance, and only by understanding the morphogenesis of these anomalies may findings indicating their presence be properly interpreted.

Dr. Braasch, in spite of my efforts, still refers to anomalies of Form, Position and Number. This old classification is arbitrary and does not take into account facts of development. Some time ago I submitted a new classification based on the morphogenesis of these malformations. According to this, anomalies of the upper urinary tract are divided into three groups according to the primitive organ from which the malformed structure derived: (1) The Renal Blastema (kidney proper). (2) The Wolffian Duct (ureter, pelvis, calices, excreting ducts). (3) The Vascular Channels (renal blood vessels).

In the first group belong the anomalies of form, such as lobulated kidney, polycystic kidney and the fusion malformations such as horseshoe kidney, unilateral fused kidney and malpositions such as ectopia and malrotation of the sort described by Dr. Braasch.

In the second group belong the cleavage anomalies, usually referred to as duplications, complete or partial. Abnormal position of the ureteral opening within the bladder, urethra, genital tract or rectum also falls into this second group. It includes also those structural narrowings of the excretory channels occurring as congenital strictures of the ureter, uretero-pelvic junction or calices. The third group is comprised of anomalies of the renal vascularization.

Dr. Braasch enthusiastically approved of this classification when it was first presented.

There is one point in regard to the interpretation of pyelograms showing under rotation of the kidney which Dr. Braasch did not mention, but one which is of great aid in recognizing the exact condition present. Whether or not attention has been called to it by others, I do not know. As indicated by Dr. Braasch, there may be malrotation either alone or in conjunction with fusion. It is of great importance to differentiate between the two. Even with a pyelogram on only one side, the differentiation may usually be made by the presence or absence of what I have called the normal "axial deflection of the kidney." When the kidney is first formed down near the lower end of the Wolffian duct and during the early part of its ascent, its axis is oblique from above toward the midline below. During the latter part of ascent this axis is deflected and becomes oblique, from below toward the midline, above. With simple under rotation this normal axial deflection is present. Fusion of the two kidneys prevents this occurrence and axial deflection is absent. Thus the presence or absence of normal axial deflection is a criterion for differentiating between simple under rotation and fusion anomaly.

Dr. R. E. Scammon (Minneapolis): I don't know that I can add much to the discussion. Problems of this kind interest the embryologist very much and we all appreciate their being brought to our attention. When one considers the number of things that take place in the development of the kidney, it is not surprising that we find these anomalies. Most anomalies consist either of structural defects, occasionally growth anomalies, or of perversions of position. The kidney is one of the organs which may have all of these developmental defects. The kidney is also peculiar in the respect that these anomalies occur much later than is usual, *i.e.,* between about the fourth week and, perhaps, the sixth week after conception. These anomalies of the kidney are, most of them, a good deal later —a matter of later embryonic period or extending into fetal life.

So far as I know, we find deflections or rotations of major importance in the body in the following places: in the heart, in the gastro-intestinal tract, in the uterovaginal canal, and this one just pointed out in the kidney. These are the main places where we find a deflection by axis rotation. It seems to me we know very little about these deflections in the axes of organs or systems. The mechanism of heart rotation seems to fit fairly well with certain known principles of hydrostatics. The anomalies that we find in the uterovaginal system seem to occur very much later and are probably tied up with the rapid growth of the pelvic colon and certain other pelvic viscera. But we know much less of these anomalies of axial positions of the gastrointestinal tract and the kidneys and ureters. Some work done by Cary indicates that rotation of the gastrointestinal tract is probably an interstitial matter; that it is not due to mechanical pressure but to the fact that the cells of the tract grow in very definite zones. Why this is so, we do not know. It seems quite probable that this unequal growth is responsible for the rotation of the digestive tract. I am inclined to think that if we had an analysis of this kind for the kidney and ureter, we might find the same thing to be true.

The secondary changes that we get in fetal life do not seem to be tied up with pressure. I am inclined to think that these very interesting anomalies will be found to be tied up with the rates of growth in certain zones; that some parts of the tract have marked powers of growth and some practically stand still. I would suggest that this is probably where we are going to find the explanation for these interesting anomalies; that it is in some growth phenomenon rather than in some mechanical phenomenon that we will find the true cause of these modifications in development.

Dr. Arnold Schwyzer (St. Paul): It just occurred to me (while listening to Dr. Foley's remarks) whether it could not be that this inward rotation of the upper pole, while the kidney gradually ascends, is due to the pivoting around the origin of the renal artery. The renal artery with its different branches holds the kidney while it ascends, so that, when the kidney comes up, the artery with its branches would rotate the pole. Perhaps the blood waves through the branches have a mechanical action to steady the distance of the poles from the main artery. I wonder whether there would be anything to that view.

Dr. William F. Braasch: I am certainly very grateful for the generous discussion of my paper. In answer to the last suggestion made by Dr. Schwyzer, one man's theory is probably as good as another's and that appeals to me as a very plausible one. In reply to Dr. Foley, I will say that I still think his classification is a good one and I tried to use it in this paper, but found this was so broad that I could not, and had

to go back to the old form. I hope this paper may have aroused some interest in this rather unusual field.

Dr. Charles N. Spratt (Minneapolis) read his thesis entitled "A Review of 100 Cases of Intraocular Foreign Bodies." Lantern slides and various instruments were shown.

Dr. Spratt: At this time it is proper and right that I should acknowledge my appreciation of election to this ancient and honorable body. In February I completed 25 years in the practice of medicine in this city and this comes as a sort of consummation of that event. In that 25 years I have seen 22,400 patients, two-thirds of them eye patients. Among the latter were 98 individuals who had intraocular foreign bodies; 3 had foreign bodies in both eyes, making 101 cases of intraocular foreign bodies.

DISCUSSION

Dr. John F. Fulton (St. Paul): I rise more for the purpose of congratulating the Academy on having Dr. Spratt as one of its members and to bid him a joyful welcome rather than to take part in the discussion of his paper. The contribution which he has given us is a very valuable one, as much so as any ophthalmologist that ever contributed to the Academy. I shall not enter into the history of methods of treatment of intraocular foreign bodies but refer you to a very excellent and reliable paper by Walter V. Moore, of Brooklyn, published in the 1924 volume of the American Journal of Ophthalmology in which he gives credit to Dr. Nikolous Meyer as being the first to extract steel from the eye with a magnet. He quotes from the original paper by the author in which he says that he succeeded in removing a needle-shaped piece of steel after having failed to remove it by means of the usual instruments, saying that he combated the subsequent inflammation by the use of leeches and cold packs. The two great leaders who developed and popularized the use of the magnet for removing foreign bodies from the eye were Julius Hirchberg, of Berlin, and Haab, of Zurich. Hirchberg became dissatisfied with the fixed magnet as being clumsy and inconvenient so he invented the electromagnet, removing foreign bodies by opening the vitreous chamber when situated in that part of the eye. We are using about the same magnet today with the addition of greater power as demonstrated by the Sweet magnet. Dr. Haab, not being satisfied with the magnets in use, invented his giant magnet which he demonstrated at the Ophthalmological Congress in Heidelberg in 1902. His idea was to add power to the instrument, believing that the greater the power the better the chances for success. He strongly recommended always to remove the foreign body through the route that it entered, opposing posterior sclerotomy.

A few years ago it occurred to Dr. Jackson that the magnet could only remove foreign bodies when it was able to overcome the grip of the ocular tissues and he maintained that it was just as important to loosen this grip as to increase the power of the instrument; so he suggested the use of the electromagnet scissors for this purpose, and succeeded in obtaining excellent results in this way when the magnet itself failed.

Only a few reports such as Dr. Spratt has given us tonight have been published. Haab reported 165 cases; failed in 25 of this number; and succeeded in removing the foreign body from 141. He enucleated 39. Cataract developed in 71, extraction of which produced excellent results in 51. Fisher, of Chicago, reported 150 cases, in 4 of which steel was found in the eyeball after enucleation. He obtained good results in 96 of these cases. The excellent results obtained by the reports here briefly analyzed, together with the very excellent analysis made by Dr. Spratt this evening, indicate the most gratifying results obtainable by the magnet. This is all the more wonderful when I remember that before its invention the very best oculists claimed that a foreign body in the vitreous chamber demanded enucleation. Criedland recently reported 76 cases, of which 43 were saved and 33 enucleated. His results demonstrated that the more anterior the foreign body was located the better the results. Twelve of his cases developed cataracts, 10 of which were successfully removed with complete restoration of sight. He always waited until the opacification was complete before extraction. Clinical experience demonstrates that the lens is more tolerant to foreign bodies than any other part of the eye. I refer you to a paper by Dr. Nikolaus Blatt, of Transylvania, published in the February number of the American Journal of Ophthalmology, in which he carefully points out the importance of conservatism in treating foreign bodies located in the lens.

Dr. Frank Burch (St. Paul): We have much enjoyed this presentation by the essayist. One point learned from experience is concerning the presence of a foreign body in so-called idiopathic iritis. In 6 instances which I can recall, an apparently idiopathic iritis was found to have been caused by an intraocular foreign body. Only by a careful history of what transpired preceding the iritis can the possibility of a retained foreign body be disclosed. Two of my cases were in children, and in each instance what might have been a serious affair, as regards the future of the eyes involved, was prevented by the discovery of a foreign body within the eye, in one instance with the aid of the *x*-rays. In one case of a man who had developed an extremely persistent iritis with hypopyon, the condition was treated for three weeks with careful study for focal and systemic infection, until a more careful inquiry revealed the fact that three weeks preceding the onset of inflammation he had been hammering a plowshare and had felt something strike his eye with only temporary irritation. He had not associated the late inflammation with the previous injury.

In two other instances the patients could not even remember having received any injury although in one case the ophthalmoscope, and in the other the *x*-ray, revealed the presence of a foreign body in the choroid. The history of every patient with iritis should be carefully taken to cover such contingency.

The tolerance of the eye for metallic as well as nonmetallic foreign bodies is at times very surprising. In one instance a piece of glass penetrated the eye following a laboratory explosion and was retained about three

years until it was successfully removed with preservation of vision. Twice during the past few years encysted cilia have been removed after entering the eye through incised wounds of the cornea. A few weeks ago my associate removed a piece of steel from the lens of an eye which had remained there for about a year and had developed cataract, but at no time was there any severe reaction in the eye. Copper is peculiarly prone to cause disturbance. I have in the hospital at this time, a patient with copper retained within the eye in whom I have successfully removed a cataract without any inflammatory reaction. I believe he will eventually develop iridocyclitis as copper produces chemical changes which seem to be extremely irritating. Copper will produce a leukocytic pus within the eye without actual infection. In 8 or 9 shot cases which I have seen there has never been a case of sympathetic ophthalmia. In fact, I have never personally seen but one case of sympathetic ophthalmia following retained foreign body.

Dr. Spratt mentioned a subject which I would like to discuss further, namely, the fallibility of the *x*-ray localization. Once in my experience the *x*-ray examination did not reveal a foreign body; in another the triangulation showed the foreign body to be outside the globe. In both instances siderosis subsequently developed and in one of the patients enucleation was necessary. As Dr. Spratt mentioned, repeated *x*-ray examinations should be made, when necessary, if the history indicates the possibility of a foreign body. Also I know of cases where foreign bodies have been reported which could not be removed with a magnet. The eyes were removed and the foreign body was found embedded in the sclera in a harmless position. The difference of 0.5 mm. in triangulation measurements is sometimes a very important matter.

A hopeful phase of this subject is the fact that fewer foreign bodies in the vitreous are being seen because more men are wearing goggles in their work, and the use of non-shatterable glass in goggles affords added protection. Unfortunately most of the accidents we see are in garages or in industrial plants where these precautions are not observed. I believe in some states the Industrial Commissions insist on the observance of all precautionary measures, including goggles, if the employees are to receive compensation for external or for intraocular foreign-body injuries.

Dr. John Brown (St. Paul): One thing has appealed to me which I do not know whether or not Dr. Spratt has thought of, and that is the tolerance, or intolerance, for foreign bodies for the individual in the eye itself. There is something inherent in the individual himself which makes this tolerance to a foreign body, when another one would not tolerate it at all, and whose eye may go on from bad to worse before the patient arrived at the oculist's. In my experience the young individual is much more prone to these disturbances than the adult. I presume the lens structure has more resistance in adults. In many instances you will have loss of the lens substance if the foreign body pricked the lens and many go on to cataract. I am beginning to feel that an adult with a foreign body in the eye is a much better risk than is the juvenile.

Dr. Spratt (in closing): This subject, of course, is so interesting to ophthalmologists, that we could talk all night. Each case is a story in itself. I have seen two cases with cilia in the eye and left them alone. They are not included in this series. There were two or three in this series that did not know they had a foreign body in the eye. One boy was hanging around a blacksmith shop, and later developed pink-eye, which, however, proved to be an intraocular foreign body. The important points of the whole subject are these: (1) Is the foreign body clean or dirty? (2) Whether it is clean or dirty, the accurate localization is absolutely essential if you are going to treat it properly. If it is back of the eye, leave it alone.

Dr. Fulton: Did any of those patients have glass in the eye?

Dr. Spratt: There was no glass; four of them had pieces of granite.

Dr. T. A. Peppard (Minneapolis) read his Thesis on "Pericarditis" and showed lantern slides.

The meeting adjourned.

R. T. La Vake, M.D., Secretary.

TRANSACTIONS OF MINNEAPOLIS SURGICAL SOCIETY

Meeting of April 3, 1930

The monthly scientific meeting of the Minneapolis Surgical Society was held in the Lounge of the Hennepin County Medical Society April 3 at 8 P. M. with the president Dr. S. R. Maxeiner presiding.

Dr. Martin Nordland presented a paper on "The Larynx—Its Relation to Thyroid Surgery." This showed much original work in the way of anatomical dissection as well as conclusions drawn from his wide surgical experience. This paper has been accepted for publication in the Journal of Surgery, Gynecology and Obstetrics and will appear in a future issue of that journal.

The discussion of Dr. Nordland's paper was opened by Drs. Fowler and Hanson.

DISCUSSION

Dr. L. Haynes Fowler: I first became particularly interested in the anatomy of the superior laryngeal nerve several years ago when Dr. William A. Hanson and I dissected over two hundred thryoid glands, the results of which were reported in a paper read before this society in October, 1928, and published in Surgery, Gynecology and Obstetrics July, 1929. In that work our efforts were directed especially toward establishing more accurate information regarding the relations of the recurrent or inferior laryngeal nerve. However, we did at that time note the very close relation between the superior laryngeal nerve and the upper pole of the thyroid gland and expressed the opinion that injury to this nerve might be the cause of some of our postoperative vocal disturbances.

This is demonstrated by the results of the work which Dr. Nordland has given us to-night. He has shown very clearly the close relation of the internal branch of the superior laryngeal nerve to the upper pole of the thyroid gland, and secondly has demonstrated that this nerve supplies motor fibers to the interarytenoid muscle, instead of being a purely sensory nerve to the larynx.

To me this means therefore that we can no longer handle the superior pole of the thyroid gland with impunity but that we shall have to consider the branches of the superior laryngeal nerve as well as those of the recurrent laryngeal nerve a real source of danger in thyroidectomy and govern our operative technic accordingly.

Dr. William A. Hanson: We are much interested in this anatomical and physiological report regarding the external laryngeal nerve, a branch of the superior laryngeal nerve. This nerve, as we found it, passes obliquely downward and medially, crossing posterior to the internal and external carotid arteries and between the upper pole of the thyroid and the lamina of the thyroid cartilage, and innervates the cricothyroid muscle. Here we have a close relation to the superior thyroid arteries.

The physiology of the nerve is not definitely known. Experimental work by cutting this nerve has been done in dogs but no effects on the vocal cords were produced.

We called attention to this nerve in our report on the surgical anatomy of the thyroid gland with special reference to the relation of the recurrent laryngeal nerve which we presented before this Society in October, 1929, starting a further investigation of the nerve in order to determine whether or not we are overlooking a definite anatomical structure, injury to which may be causing some post-operative vocal disturbances, and shall be interested to know what conclusions Dr. Nordland finds in his problem regarding the physiology of the external laryngeal nerve.

In 262 of our 400 cases, or 65%, the nerve passed posterior to main branches of the inferior thyroid artery, and in 104 of 400 cases, or 26 per cent, it passed anterior to the main branches of the inferior thyroid artery. In 34 cases, or 8.5 per cent, it passed between the main branches of the inferior thyroid artery.

Dr. E. K. Green presented a case report of an unusual case of acute intestinal obstruction.

A CASE OF ACUTE INTESTINAL OBSTRUCTION

Dr. E. K. Green: The following is the report of a case of acute intestinal obstruction in a girl twelve years of age resulting from a chronic intussusception which gave irregular symptoms for about two weeks.

There was no history of previous attacks except when she was about six years of age her mother said she had had a stomach upset which lasted four or five days.

She was first seen in this attack November 3, 1929, at which time she had a little nausea and slight abdominal pain. Between then and Nov. 12, 1929, she was seen twice and at no time was there any definite signs of impending danger. Her symptoms were those of nausea, irregular pain, diarrhea at times, and again was entirely free from symptoms to such an extent that she had a party for some of her friends. Her mother was a Christian Scientist and consequently minimized her symptoms and gave very little coöperation. On November 14, 1929, after about twenty-four hours of severe come-and-go pains with nausea, some vomiting and obstipation, she presented a very different picture. She was very definitely dehydrated and her abdomen was distended. Her pulse was 130 or more. Dr. C. W. Pettit, who had been in charge of the case, then made a very positive diagnosis of acute obstruction and sent her to the hospital for immediate operation.

My reason for reporting this case is to show how, in desperate cases, with conservative methods and careful management, we are able to get by and obtain a final recovery.

At the first operation we found about twelve or fifteen inches of terminal ilium intussuscepted into itself forming a tumor nearly the size of the fist, which was held by light adhesions in the pelvis. On lifting it out, we found about 1.5 inches of collapsed ileum proximal to the ileocecal valve and a Meckel's diverticulum just proximal to the tumor. The proximal ileum was greatly distended, thickened and filled with a semi-liquid which was impossible to remove with a sucker. In our efforts to untangle the intussusception, we found the bowel ulcerated through, making it impossible to prevent the escape of feces. Because of her desperate condition, we stitched the gut to the wound and drained the proximal loop.

By way of management, when she came to the hospital, while setting up the operating room, we gave her 1,000 c.c. of normal saline under the skin. As soon as she was returned to her room, after the operation, we gave her 1,000 c.c. of 3 per cent salt and 1,000 c.c. of normal saline. She took, in addition, 2,000 c.c. by mouth during the first twenty-four hours. She weighed only about 60 pounds and with 5,000 c.c. of water within twenty-four hours, she reacted very nicely. During the next eighteen days our only effort was to get her in shape for the ultimate removal of the tumor and anastomosis of the gut. Once we took her to the operating room to untangle the intussusception to relieve her of constant pain and discomfort. We made an effort to close the gut at that time, but it soon ulcerated through.

As we were about to do the final operation, we were delayed for a few days because of a bowel upset in which she had numerous watery irritating stools. On December 2, 1929, we did the final operation which consisted in removing the gut in the intussusception with its mesentery and uniting the cut ends. Because of the short distal loop of the ileum, I used a Murphy button for the anastomosis and to our surprise the abdominal wound united by first intention and there were no signs at any time of either local or general peritonitis. The patient passed the button on the seventh day and aside from mild symptoms of obstruction for about twelve hours, two days later, she made an uncomplicated recovery.

The discussion of Dr. Green's case report was opened by Dr. Owen Wangensteen.

DISCUSSION

Dr. Owen H. Wangensteen: Dr. Green's case is interesting from several standpoints. Intussusception occurs most frequently between the fifth and ninth months of life. About 75 per cent of bowel invagination occurs during the first two years of life. Its occurrence in male infants is three times more frequent than in females. After the age of three, intussusception is relatively infrequent and an inciting agent in the nature of Meckel's diverticulum or a tumor in the bowel is frequently present. In patients suffering from intussusception who have passed the age during which telescoping of the bowel is common, such a predisposing mechanism as was present in Dr. Green's case is to be suspected. Eliot and Corcasden in a review of 300 cases of intussusception in adolescents and adults found a tumor or a Meckel's diverticulum to be present in one-third of the cases. Benign tumors are more frequent offenders than malignant neoplasms and the small intestine more often concerned than is the colon in cases of intussusception at this time of life. Chronic or recurrent intussusception is more prone to occur in adolescents and adults and a tumor of the bowel is not an unusual finding in such cases.

In irreducible intussusceptions of the type presented by Dr. Green, excision with primary anastomosis or exteriorization are the Surgeon's only alternative. In a poor risk, Dr. Green's choice of exteriorization carries the lesser risk. The performance of an intestinal anastomosis in the presence of an acutely distended intestine is a hazardous undertaking and is to be religiously avoided. If the temporary fistula in the bowel proves to be high, the content discharged from the proximal loop is to be collected and poured into the distal through a urethral catheter. A patient can be tided through a crisis by this compromise and an intestinal anastomosis more safely made at a later date.

Infants with intussusception stand intestinal resection very badly and a non-viable segment in such a patient is synonymous with an extremely bad prognosis. In 1913, Dowd could find but eight cases under one year of age that had survived intestinal resection for bowel invagination.

In an invaginated bowel in which the intussusception is viable but not reducible, a maneuveur suggested by H. P. Brown of Philadelphia in 1926 appears to be especially meritorious; calling attention to the fact that the edematous neck of the intussuscipiens or ensheathing layer prevents the reduction of the apex of the intussusception, he cuts the cuff of the ensheathing layer with scissors which permits of prompt reduction. The resulting linear incision is then closed with Lembert sutures.

Almost universally in our textbooks of surgery, operative reduction is extolled as the only safe method of dealing with intussusception. Recently, however, Hipsley of Sydney, Australia, who to date can boast a better result in the operative treatment of intussusception than any surgeon with whose reports I am familiar, has not only had success with the non-operative method but forcibly states that no surgeon should have recourse to surgery without giving the non-operative method a trial. In the Medical Journal of Australia for 1918, Hipsley reports 51 consecutive successes with operation for intussusception in patients whose duration of symptoms was under thirty-six hours. Despite this admirable result, in a subsequent larger series reported in 1926 he finds the conservative method of reduction by water enemas at a gravity pressure of 3.5 feet to be successful in 62 per cent of instances.

Hirschsprung popularized the method many years ago at the Queen Louise Hospital in Copenhagen, but the method has never received universal approval. Hirschsprung as well as his successor, Monrad, employed chloroform anesthesia and combined enemas with manipulative taxis through the abdominal wall.

The advocates of the method limit the employment of this procedure, however, to colic types of bowel invagination alone; 75 per cent of intussusceptions being of the ileo-cecal variety (the caput caeci constituting the apex of the intussusceptum) the majority of instances are amenable to a non-operative attempt at reduction. Intussusception of the small intestine, viz., pure enteric types as the one reported by Dr. Green, and ileo-colic intussusceptions are not suitable. The "Achilles' heel" in Hirschsprung's method is that natural evacuation of the bowel has to be awaited to confirm a satisfactory and complete reduction, a decidedly unsafe criterion.

Pallin and Olsson of Key's Clinic in Stockholm have employed the hydrostatic pressure of a barium enema to accomplish the reduction in colonic types of intussusception as well as for immediate fluoroscopic control of complete reduction. During the past year at the University Hospital we have had an unusually large and interesting group of cases of intestinal obstruction and among them several cases of intussusception. We have employed this method with success and can endorse its use for colonic types of intussusception. The barium enema method not only shows the defect present but serves as an immediate control of adequate reduction. If the method fails, no harm has been done and resort can be had to operation without serious loss of time.

Dr. Stanley Maxeiner: There is one point that I should like to call attention to concerning the diagnosis of intestinal obstruction in general, viz., the unreliability of enemas as a diagnostic criterion of the existence of intestinal obstruction. There exists a general unwillingness to accept the diagnosis of intestinal obstruction as long as the patient expels an enema with the return of gas and feces. Recently, together with the aid of Mr. Goehl, a Senior Medical student, I established complete obstructions in dogs by cutting the small intestine across and inverting the ends. Invariably these dogs expelled gas following the administration of Noble's enemas. When a catheter was threaded into the distal segment and barium introduced, its transit through this distal bowel was accomplished in normal time. Dr. Herbert A. Carlson and I have since put balloons into the distal segments of dogs with complete obstructions and observed that the contractility of this bowel is much like the normal. The bowel

distal to the obstruction is physiologically as well as anatomically normal. Why shouldn't it expel gas following the administration of an enema?

In a complete low obstruction, enemas may continue to serve as a fairly reliable index of bowel obstruction, but in high obstructions as well as in partial obstructions it is a decidedly unsafe criterion. I do not deprecate their administration in suspected cases of bowel obstruction, but the interpretation of the data obtained by this means must be adjudged critically. It is a good plan to give such a patient two enemas. Unless the obstruction is low in the colon gas and feces will be returned with the first enema. If, however, no return of gas or feces is obtained with a second enema, administered half an hour after the expulsion of the first, evidence for the existence of an obstruction probably low down in the intestine is obtained. But the persistence of pain of an intermittent crampy nature, despite the return of enemas, is adequate indication for immediate operation.

The meeting adjourned at 10 P. M.

H. O. McPheeters, *Secretary.*

OBITUARY

C. Eugene Riggs

(1853-1930)

Dr. C. Eugene Riggs, Saint Paul, the first physician in the Northwest to specialize in nervous and mental diseases, died at his home, April 3, 1930. The following record of his life was dictated by Dr. Riggs some six years ago:

"Dr. C. Eugene Riggs was born in West Unity, Ohio, in 1853. He belonged to an old and well-known Maryland family whose members played prominent parts in early American history. His early education was in the public schools of Bryan, Ohio. Entered Ohio Wesleyan University in 1873; received the degree of A.B. in 1877 and that of A.M. three years later. Studied medicine in the office of his brother, Dr. J. U. Riggs of Bryan, for two years, in the good old-fashioned way. After this had one year in Medical College at Nashville, Tenn. Graduated in 1880 at the College of Physicians and Surgeons, Baltimore, Md. This was later merged in the Medical Department of the University of Maryland. Spent one year as senior interne at the Woman's Hospital, Baltimore.

"Came to St. Paul in the spring of 1881 and engaged in the general practice of medicine. The following year he was given the chair of neurology and psychiatry in the St. Paul Medical College, thus becoming the pioneer neurologist in the state of Minnesota, and when the Medical Department of the University of Minnesota was established he became professor of nervous and mental diseases. This chair he held for 25 years and at the time of his death was professor emeritus.

"September 11, 1884, he married Mabel Elizabeth Pratt, daughter of Albert M. Pratt of Bryan, Ohio. They had one daughter, Mrs. Fred Winston Long of Jacksonville, Fla.

"For ten years preceding the establishment of the State Board of Control Dr. Riggs was chairman of the State Lunacy Commission. He made repeated trips abroad for the purpose of medical study, and on one such journey was authorized by Governor Merriam to investigate the insane hospitals of Europe for the purpose of reproducing in Minnesota whatever was of value in European methods of care for the insane. He was also the first to interest himself actively in the necessity for detention wards in our larger cities, in the need of special care for the criminal insane and in the imperative necessity for a voluntary commitment law. The propaganda thus started by Dr. Riggs ultimately brought about all these needed reforms in the state. He also was the first one to use the intraspinous medication in the West.

"Dr. Riggs was a member of the American Neurological Association, the American Psychiatric Association, Minnesota Academy of Medicine, Minnesota Neurological Society, the Ramsey County Medical Society and the Central Neuropsychiatric Association.

"He was also a member of the Society of Colonial Wars and of the Sons of the Revolution, of which he had been president, and of the Minnesota Club.

"Dr. Riggs was a member of Plymouth Congregational Church, Minneapolis.

"He was a member of Summit Lodge and a Past Master, also member of Osman Temple and Paladin Commandery, and was a thirty-second degree Mason."

He is survived by his daughter in Jacksonville, Fla., two grandchildren, Mary Winston and Charles Riggs Long, and his nephew, Dr. Charles Riggs Ball of St. Paul.

Aloysius Julius Kaufman

(1875-1930)

Dr. A. J. Kaufman, a practising physician of Franklin, Minnesota, where he had practised for the last seven years, died suddenly March 23, 1930, at his home of heart disease at the age of 55 years.

Dr. Kaufman was born in Passau, Bavaria, Germany, and received his early education there. In 1886, he came to Newark, N. J., where he attended a seminary and then entered the University of Pennsylvania Medical School, from which he graduated in 1899. He practised in Colorado, Portland, Oregon, and then at Cheyenne Wells, Colorado, where he had a hospital for ten years. In 1923, he came to Franklin, where he also had a hospital.

He is survived by his wife, and two daughters, Anna and Margaret Kaufmann.

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

BOOKS RECEIVED FOR REVIEW

CANCER OF THE BREAST. William Crawford White, M.D., F.A.C.S., Junior Surgeon to the Roosevelt Hospital, Consulting Surgeon to the New York Nursery and Child's Hospital. 221 pages. Illus. Price $3.00. New York: Harper & Brothers, 1930.

THE NORMAL DIET. W. D. Sansum, M.S., M.D., F.A.C.P., Director of the Potter Metabolic Clinic, Department of Metabolism, Santa Barbara Cottage Hospital. 3rd Ed. 134 pages. Illus. Price $1.50. St. Louis: The C. V. Mosby Company, 1930.

GONORRHEA AND KINDRED INFECTIONS. George Robertson Livermore, M.D., F.A.C.S., Professor of Urology, Medical Department, University of Tennessee, etc., and Edward Armin Schumann, A.B., M.D., F.A.C.S., Associate Professor of Obstetrics, University of Pennsylvania, etc. 257 pages; 66 illustrations. $5.00. D. Appleton and Co., New York and London, 1929.

As the authors state, this rather short but practical work is a presentation of their personal experience and conclusions regarding the diagnosis and treatment of gonorrhea. Comparatively few references are made to the literature on the subject. Particular attention is paid to pathology. The various means of diagnosis are carefully described. Methods of treatment are covered briefly, with, in most cases, an indication of the preferences of the authors. Since there is a wide divergence of opinion as to the choice of methods, naturally the reviewer does not agree with the authors in some details. Still the methods advocated are based on sound reasoning and wide experience and must carry weight on that basis.

The arrangement of the subject matter is practical, and the table of contents and the index aid also in making this an especially valuable reference book in a practitioner's office.

T. H. SWEETSER, M.D.

WANTED—Salaried appointments for Class A Physicians in all branches of the medical profession. Let us put you in touch with the best man for your opening. Our nation-wide connections enable us to give superior service. Aznoe's National Physicians' Exchange, 30 North Michigan Ave., Chicago. Established 1896. Member The Chicago Association of Commerce.

WANTED—REPRESENTATIVES—Desirable territory open for qualified men to call on doctors, dentists and pharmacists; immediate and permanent work. Lea & Febiger, S. Washington Square, Philadelphia, Pa.

WANTED—Physician for locum tenens, six weeks, starting July 1, Southern Minnesota town, 1,000 population. Address D-68, care MINNESOTA MEDICINE.

WANTED—X-ray and laboratory position. Competent young lady with three years' experience in X-ray and routine laboratory work, desires position in doctor's office or community hospital. Two years' nurse's training. Some knowledge of physical therapy. Best of references. Address D-68, care MINNESOTA MEDICINE.

WANTED—Summer work as medical technician desired. Have had some experience. References given if desired. Margaret Sutermesiter, 1121 Seventh St. S.E., Minneapolis, Minnesota.

FOR RENT—Best corner in city, occupied by doctors 40 years. Inquire J. E. Kinsella, Room 8, 601-5 St. Germain Street, St. Cloud, Minnesota.

POSITION WANTED in physician's office in or near Twin Cities by young woman physiotherapy technician. Can run urinalyses, make blood counts, also some *x*-ray. Eight years experience. Address D-65 care MINNESOTA MEDICINE.

SITUATION WANTED—*X*-Ray and laboratory technician, woman age 25, graduate of Swedish Hospital School of Technicians, Minneapolis. Have had three months experience in doctor's office. Can use typewriter. Address Box 222, Lamberton, Minnesota.

PHYSICIAN'S OFFICE FOR RENT—Best location Midway district, corner Thomas and Hamline. Rent $25 a month. Inquire at dentist's office.

WANTED—Locum Tenens or assistantship by experienced physician, licensed in Minnesota. Address D-66, care MINNESOTA MEDICINE.

WANTED—Staff physician for Minnesota State Hospital. Either single or married man. Suitable accommodations for married man will be furnished with maintenance. Salary $150 monthly. Address D-64, care MINNESOTA MEDICINE.

ESSENTIAL HYPERTENSION — PARTICULARLY STRESSING THE SIGNIFICANCE OF DIASTOLIC BLOOD PRESSURE*

C. N. McCloud, M.D.
Saint Paul

ESSENTIAL hypertension has attracted a great deal of attention during the past decade, and is now generally recognized as a definite clinical entity, being more clearly differentiated from other diseases in which abnormally high blood pressure is a symptom. It was not until 1906 that blood pressure instruments were perfected and simplified so that they might be utilized by the average physician. Life insurance companies early recognized the value of taking the blood pressure, and set about to instruct their examiners as to proper technic and also endeavored to popularize the procedure as a routine measure to be used not only in insurance examinations but clinically as well. It was not, however, until 1918 that the companies realized that the diastolic pressure was as important as the systolic; this being stimulated by the adoption of the auscultatory method which about that time replaced the palpatory method.

In the consideration of the subject of hypertension, we have first to remember that the blood pressure is extremely variable in many individuals. It may vary from month to month, from week to week, and even from hour to hour in some individuals. As a general rule, however, the diastolic will be found to be much more constant than the systolic, and I believe of much more prognostic importance.

Since the technic for taking the systolic measurements was described at a much earlier date than the diastolic, it has, until of late, been the habit with the profession to be complacently satisfied with the taking of the systolic alone. This is unfortunate, and to those who believe the diastolic to be of greater significance, it is rather disappointing to observe how often no mention whatever is made of the diastolic pressure either by research workers or clinicians. An immense amount of study has been done regarding hypertension in large groups of individuals, both in institutions and in clinics. These individuals were studied over long periods of time and with great expenditure of effort, and yet so simple a procedure as to include in these studies the taking of diastolic pressures has been lamentably disregarded. This is unfortunate because in our opinion the information secured from the taking of both systolic and diastolic pressures is of incomparably more value than that which can be obtained by gauging the systolic pressure alone.

Reisman and Weiss in the current number of "American Heart Journal" dismiss the subject of diastolic blood pressure with one short paragraph. "A patient may be considered to be suffering from hypertension who has a diastolic pressure in the neighborhood of 100 mm. hg., though the systolic is only moderately elevated."

We believe that, as we learn more about the dynamics of the circulation, the diastolic pressure will come to be, for prognostic and clinical purposes, paramount in importance. Weiss states:

"Of all the information obtained in blood pressure estimation, the diastolic pressure is the most constant. It is less influenced by such factors as rest, exercise, diet, time of day, etc. When it does vary, the fluctuation is not so great, it gives more reliable information than the systolic or the pulse pressure."

It is unquestionably true that the reason the diastolic pressure was so long ignored is that the technic for taking the systolic measurements

*President's Address read before the Minnesota Academy of Medicine, January 8, 1930.

was described at a much earlier date than that for taking the diastolic and that it has been difficult to obtain proper readings. This has been very evident to insurance companies, whose experience shows that there is no uniformity in technic, some examiners recording their observations at the fourth phase (at the change of sound) and some at the fifth phase (or the disappearance of all sound).

It has been shown that most medical schools teach their students to observe the diastolic pressure at the fourth phase (at the change of sound), but owing to the fact that many physicians have no "tone sense" and that others for various reasons are unable to accurately detect the *change* of sound, it has become an almost universal practice for insurance companies to instruct their examiners to record the diastolic pressure at the disappearance of all sound (fifth phase), for the reason that it is best understood and certainly more generally used.

It is true that whether one or the other phase is used, there is a difference of only about 4 mm. hg. in the average case, but, owing to the attempted exactitude of insurance companies for statistical and practical considerations, this 4 mm. hg. may mean the difference between the rejection or the acceptance of risks which are borderline as to their blood pressure.

Our knowledge of and confidence in the ability of our examiners are very important factors in estimating the value of the readings given. It occasionally happens that very extraordinary pressures are reported such as systolic 130, diastolic 120. This disturbs our confidence in the ability and progressiveness of an examiner much more than it does the question of the insurability of the applicant. Fortunately, the number of physicians recording such impossible readings is rapidly decreasing. I trust I may be pardoned at this time for reviewing the technic concerning the various phases of blood pressure estimations:

First Phase—Is of short duration, often difficult to detect. Sounds are soft and dull.

Second Phase—Extends over a range of from 20 to 60 mm. hg. The quality of the sounds is variable, and it is here the silent gap occurs when present.

Third Phase—Most distinctive phase. Here the sounds are loud and snappy, increasing in intensity to a maximum when they suddenly change to fourth phase.

Fourth Phase—Of short duration; sounds soft and dull.

Fifth Phase—Sounds disappear altogether.

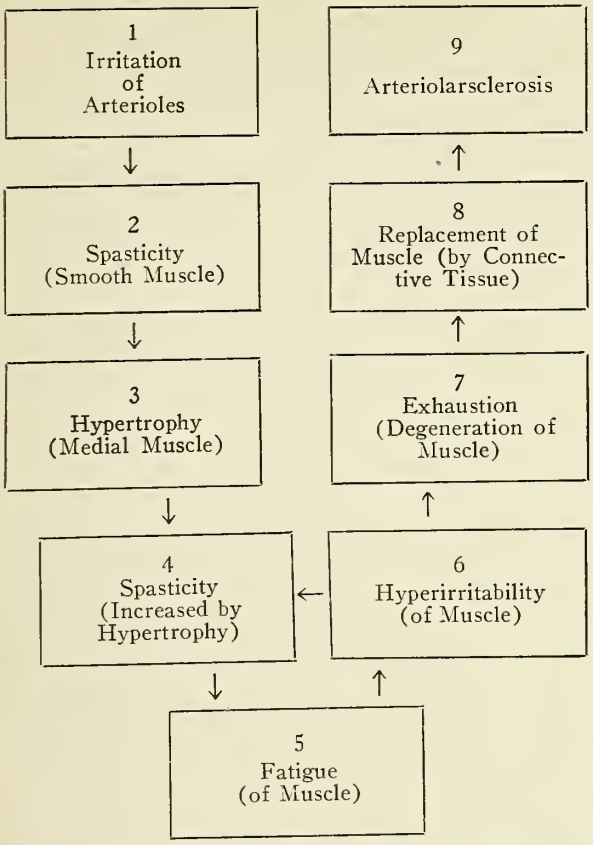
AVERAGE DIASTOLIC PRESSURE

20,735 Cases

Fourth and Fifth Phases

		October 1922 4th Phase	*October 1923 5th Phase*
Age	20	78	73
	25	79	74
	30	80	75
	35	81	76
	40	81	76
	45	82	77
	50	83	78
	55	84	79
	60	85	80

Warfield states "that until recently there was no unanimity of opinion concerning the point where the diastolic pressure should be read." Korotkov himself thought it should be the fourth phase. Fischer, Lang and Manswatona agreed. Ettinger maintained that the end of the fourth phase, or at the disappearance of all sound, was the place to take the diastolic reading. American investigators followed his lead.



AVERAGE BLOOD PRESSURE

Graduated results for quinquennial ages in group 545,121 cases, showing average systolic and diastolic (fifth phase) pulse pressures.

Age	*Systolic*	*Diastolic*	*Pulse Pressure*
20	120	79	41
25	121	80	41
30	123	81	42
35	124	82	42
40	125	83	42
45	127	84	43
50	129	85	44
55	131	86	45
60	134	87	47

PATHOGENESIS

I have recently been privileged to have presented to me a graphic outline of what I regard as a most lucid illustration of the changes which probably occur in the circulatory system where hypertension exists. The following data were furnished me by Dr. E. J. Stieglitz, who has done a great amount of research work in connection with hypertension, and I feel greatly indebted to him for permitting me to present his theories concerning this phenomena at this time:

The vicious circle of fatigue or the perpetuating factor is represented by steps 4—5—6—4.

BLOOD PRESSURE

The diastolic tension represents the peripheral resistance to the circulation and therefore indirectly is an expression of the tonus of the arterioles. Hypertension is an *arteriolar* disease. The systolic tension represents the diastolic resistance *plus* the force of the left ventricle to overcome this resistance. Therefore, in the absence of thyrotoxicosis or aortic valvular disease a liberal pulse pressure is desirable.

The diagram represents a crude attempt at visualizing the "pathogenesis of the arteriolar changes in hypertension."

Step 1

There occurs *irritation* of the arterioles by almost anything (toxins, protein excess, bacterial poisons, condiments, vasomotor hypertonia, etc.), which results, of course, in

Step 2

Increased tonus or *spasticity* of the smooth muscle of mesial layer of the arterioles.

Step 3

If such increased tonus continues any length of time hypertrophy of the muscle is inevitable, as *hypertrophy follows increased work* anywhere.

Step 4

Because of such hypertrophy, with a continuation of the original irritation, the *spasticity* becomes even more marked.

Step 5

But muscles are *not* adapted to continuous strain, as is well known, and such continuous hypertonia or spasticity leads to *fatigue.*

Step 6

Fatigue (to be sharply differentiated from exhaustion) makes muscle cells more irritable, and *hyperirritability* results.

Such hyperirritability is also seen in the nervous mechanism. We all become cranky, fussy, irritable when very tired. With such a lowered threshold mild irritation or stimulation leads to an exaggerated response of more spasticity.

Thus a *vicious circle* is set up: Steps 4—5—6—4. This is called "The perpetuating factor in hypertension," as it continues to operate, although the original sources of irritation in Step 1 have ceased to exist. It may also be termed "the vicious circle of fatigue."

Step 7

If fatigue continues to *exhaustion,* the muscle cells degenerate, die and fail. Thus simultaneously with the activity of the vicious circle, some cells are slowly exhausted.

Step 8

As these fall by the wayside, replacement with connective tissue takes place; fibrosis occurs.

This is *not* an invasive process or an aggressive cirrhosis; the connective tissue proliferates to support the crumbling framework of the vascular wall as a scaffolding to protect it. Eventually the greater portion of the arteriolar medial muscle is replaced and the final stage is

Step 9

Arteriolarsclerosis.

Up to Step 7 the processes are reversible biologically; fatigue may be relieved by rest, hypertrophy may subside. Beyond Step 7, with fibrotic replacement of *exhausted* muscle, the processes are irreversible and *not* amenable to therapy. Characteristic, of course, of the spastic earlier phases is the variability of the diastolic tension; inversely, after fibrosis occurs, diastolic tension is fixed and rigid. Therefore, we may use the variability of the diastolic tension as an index to the degree of permanent change; the more variable the diastolic tension is, the *less* the actual sclerosis.

Of course, all of these processes are slow and gradual; taking years to develop. Probably in various structures various phases of this procession occur simultaneously, and there is *no* sharp transition between the steps.

ETIOLOGY

The mere fact that the disease has been named essential hypertension is evidence that the cause is unknown. The literature is pregnant with theories as to the cause, but I shall refrain from reviewing this literature so freely referred to in several recent papers on this subject, and state in a general way that the most likely factors in producing this condition are: (1) heredity; (2)

discordant social or business life; (3) strain—mental and emotional; (4) infections and toxic conditions.

It is a fact, as Fahr points out, "that many physicians today still believe that arteriosclerosis is commonly the cause of high blood pressure. Many cases of known high blood pressure show very little or no arteriosclerosis of the palpable vessels nor does arteriosclerosis in itself increase the work of the heart. The term "arteriosclerotic heart" should be reserved for cases with coronary arteriosclerosis." A series of experiments by F. M. Smith and his co-workers led them to conclude that the rate of coronary flow is greatly altered by changes in the diastolic pressure even in the presence of changes in the systolic pressure in the *opposite direction* (i.e., low systolic pressure). They conclude that the maintenance of the essential coronary circulation is fundamentally dependent upon the height of the diastolic pressure and that while the systolic phase of blood pressure may to a certain extent influence the coronary flow, it is certainly subordinate to that of the diastolic pressure in maintaining the coronary circulation. Rountree believes "there is an unknown factor in the etiology which is not understood as yet." He is inclined to the view that "in the beginning at least the arteries are not so much at fault as they are sinned against, chiefly through the vasomotor centers and sympathetic system. Vasoconstriction in hypertension (the physiologic conception of vascular spasm) is replacing, in part, the older idea of anatomic narrowing or fibrosis; both are important, but the vasoconstrictor factor has not received the consideration it merits."

Pines, in a very classical article in the March, 1929, British Journal of Ophthalmology, believes that:

"The systolic blood pressure, although an invaluable part of the clinical picture, can be appreciated correctly only in conjunction with other clinical data. Diastolic pressure bears quite a different significance. It shows the continued pressure and, therefore, the permanent damage to the arterial wall. A continuously raised or, even worse, rising diastolic pressure means a serious prognosis. It does not fluctuate as widely as the systolic pressure; one can rely more upon it. Two men having a diastolic pressure of 130 are both under the sword of Damocles, although they may seem quite well and clinical investigation does not show signs of damage to the kidney. The retina, of course, will show in most cases the true state of affairs."

Kernohan and Keith state that "considerable controversy has existed as to whether any characteristic pathologic lesion is present in the smaller arteries. Interest in the subject was aroused by the ophthamologists being able to demonstrate so frequently a narrowing of the retinal arteries in cases of so-called malignant hypertension."

Recently these same authors have classified essential hypertension clinically into practically three groups:

1. Mild benign shows diastolic under 115 mm. hg.; no impairment of heart or kidney.

2. Severe benign, diastolic *over* 115 with evidences of impairment of vital organs and often with changes in the retina.

3. Malignant hypertension—the diastolic over 130 to 150 or higher, perhaps with marked impairment of vital organs with special changes in the retina and changes in the retinal vessels.

Insurance companies would class all three as decidedly malignant, though many of our examiners do not hesitate to freely recommend risks as first class who qualify as "mild and severe hypertension" candidates.

There is abundant evidence to show that there is at present a definite increase in the morbidity and mortality due to hypertension and its sequelæ, namely: (1) cardiac lesions; (2) apoplexy; (3) coronary diseases. The mortality statistics of life insurance companies show ample evidence of this.

From the mass of data relative to the influence of high blood pressure, there is convincing evidence that excess mortality is a function of degree of departure from normal findings. Clinical evidences, however, are convincing that a certain degree of advanced blood pressure can not in all cases have the same significance with respect to life duration, for the reason that temporary rises in blood pressure occur as a result of various *temporary* factors such as excitement, fatigue and as seen in cases of so-called "high-strung" individuals. We believe, however, that the higher *diastolic* pressure is less influenced by these factors, and when found is very significant. As a general rule when the diastolic pressure is found to have a constant reading of 100 mm. hg., we believe hypertension is present, whether

the systolic is 170 or 140, and a request is then made for further readings, and specimens of urine are submitted and examined at the Home Office laboratory.

O'Hare believes that a persistent diastolic of over 90 at ages under 40, or of 95 at ages over 40 will show a high mortality, and that a diastolic pressure of 100 or more at any age is to be considered pathologic. The persistence of raised diastolic pressure places the patient in danger of three serious sequelæ: (1) heart muscle failure; (2) cerebral hemorrhage; (3) chronic nephritis.

INSURANCE MEDICINE

In 1923 the joint committee on mortality of the Actuarial Society of America and the Association of Life Insurance Medical Directors began to investigate the effects of blood pressure on mortality; this study was completed and published in 1925. As it was not until 1918 that the companies generally required both systolic and diastolic blood pressure readings under printed instructions which were followed by examiners throughout the United States and Canada, no study was made of the subject prior to that year. During the period from 1906 to the present time, there has been a gradual education of physicians and an improvement in the technic of taking blood pressure readings. At first the systolic was taken by the palpatory method. Later it was realized that the auscultatory method was more reliable. It is, therefore, necessary to remember that the conditions under which the readings were taken differed in the various companies and that full information was necessary in order to arrange the data into homogeneous groups. The companies determined for themselves the reliability of the readings. Some took material from cases examined in the large cities by selected physicians. Others from cases examined at the Home Office and in cities where they had medical referees. Still other companies listed examiners who were known to be careful and capable of taking blood pressures accurately, irrespective of whether located in the cities or in the country. These data were contributed by twenty-five of the largest American and five of the largest Canadian companies. From these 707,000 cards (see table) were obtained. It may be said, in passing, that the insurance in force in these companies represented three-fourths of the total insurance carried in the United States and Canada. The last year of issue to be taken was 1920; observation carried to 1924. The objects of the investigation were to determine:

1. The average systolic, diastolic and pulse pressure according to weight and height of men and women.

2. The mortality according to departure from the: (a) average systolic pressure; (b) average diastolic pressure; (c) average pulse pressure.

DISTRIBUTION OF THE CARDS

		707,000 Lives		
(a)	Men—Standard lives	647,000		
	Women " "	53,000		
	Men—Substandard lives	6,500		
	Women " "	500		707,000
(b)	Systolic—Auscultatory	697,000		
	Palpatory	10,000	(all by one company)	707,000
(c)	Diastolic—Fifth phase	500,000		
	Diastolic—Fourth phase	207,000		707,000

It was to be hoped in a study of this kind from life insurance statistics that some reliable data concerning the significance of diastolic blood pressure could be presented, which would be of general interest to the medical profession. We are not at all satisfied with the results of such investigations made thus far, as, owing to the comparatively recent application of the procedure for taking diastolic pressures and the apparent neglect or indifference on the part of the profession to properly evaluate the procedure, not enough time has been allowed to elapse to draw very definite conclusions. Suffice it to state that enough material is at hand to warn medical directors, at least, to fear any case whose diastolic blood pressure hovers around 100 mm. hg. or more, for such cases will undoubtedly show a higher mortality than average.

The Committee says, "While certain conclusions have been developed they do not feel that they should specify the extent to which these are applicable to the selection of individual risks. These conclusions may be briefly stated as follows:

1. The mortality is lower than the average when the systolic or diastolic taken by itself is somewhat below the average, but no information is yet available regarding the effect of *very low* blood pressure. The average blood pressure does not, therefore, appear to be the point of lowest mortality.

2. The good effect of a systolic or diastolic

pressure slightly below the average is likely to be greater at the younger than at the older ages.

3. The mortality increases rapidly with the increase in blood pressure over the average.

4. Substantial departures from the average blood pressure are less significant in the case of pulse pressure than in the case of either systolic or diastolic pressure.

INCREASED MORTALITY OF CASES WITH ELEVATED DIASTOLIC PRESSURE

2,634 Cases

Ratio of Actual to Expected

Group A plus 10 to 16 increase in mm. Hg.....135%
Group B plus 17 to 23 increase in mm. Hg.....188%
Group C plus 24 to 30 increase in mm. Hg.....214%

	Actual Deaths	*Expected*	*Ratio*
Group A	52	38.6	135%
Group B	41	21.8	188%
Group C	24	11.2	214%

Rearranging this Material according to ages at entry:

Age	*Actual Deaths*	*Ratio of Actual to Expected*
15-39	13	115%
40-49	53	221%
50-65	51	140%

A high diastolic pressure is apparently of more importance at the middle ages of life (40-50) than at the younger or older ages.

EQUITABLE EXPERIENCE

9,280 Lives

Issues 1916 to 1924 Inclusive

Group	*Diastolic in Excess of Average for Age*
X	10 to 16 mm.
Y	17 to 23 mm.
Z	24 to 35 mm.

Ratio of Actual to Expected Deaths

CAUSES OF DEATH

Until quite recently it was generally believed that the chief cause of death as a result of hypertension was apoplexy. (Romberg states cerebral hemorrhage or thrombosis causes 45 per cent deaths in hypertension.) Fahr has recently reported that there are 140,000 persons in the United States who die each year from the consequences of high blood pressure, approximately 50 per cent due to cardiac failure consequent upon high blood pressure.

CAUSES OF DEATH

Essential Hypertension

	Heart Disease	*Apoplexy*	*Uremia*	*Miscellaneous (Intercurrent Disease)*
Bell (Myocardial insufficiency including coronary sclerosis)	60%	19.3%	8.5%	11.7%
Christian	32%	25 %	4.5%	37.5%
Granger	52%	31 %	5.5%	11 %

Mortality Investigation of Group 707,000

	9,938 Deaths	*Ratio*
Organic Heart Disease	29%	24
Apoplexy	18%	15
Bright's Disease	14%	12

According to Dr. E. T. Bell, only 10 per cent of hypertension hearts have no demonstrable coronary sclerosis. About 55 per cent show a very moderate degree of arteriosclerosis of the coronaries; 35 per cent of all hypertension hearts have moderately severe to severe arteriosclerosis of the coronary vessels. In these cases there is often very definite degeneration of part of the heart muscle with fibrosis and in these hearts the obstruction to normal volume of blood flow through the heart muscle is a serious handicap to the efficient working of the overworked heart muscle. Should a patient with high blood pressure escape apoplexy or uremia or an intercurrent death from other cause he will surely develop heart failure ultimately.

Prognosis is very difficult to estimate. Some progress rapidly to fatal ending and some live even beyond their normal expectancy of life and then die of some intercurrent disease. The essential factor is the ability of the myocardium and cerebral vessels to withstand the strain of the continued pressure.

The high diastolic pressure is of serious import, as neither the vessels nor the heart seem able to withstand a diastolic pressure of 120 mm. hg. for any great length of time.

SUMMARY AND CONCLUSIONS

1. The importance of diastolic blood pressure is seemingly not sufficiently emphasized or its significance appreciated by the profession at large.

2. Arteriolosclerosis is not an invasive process, or an aggressive sclerosis, but a replacement of muscle tissue by connective tissue—a fibrosis.

3. We would be inclined to believe that every case showing a constant diastolic blood pressure of 115 mm. hg. or over, is potentially, at least, a case of malignant hypertension.

4. Many cases of so-called "heart deaths" can be attributed to arteriolarsclerosis and are responsible to a large degree for the high mortality in the fourth and fifth decades of life. Insurance statistics show a decided rise in mortality at the ages of 40 to 50 from "heart deaths."

5. Persistent diastolic blood pressure of over 90 mm. hg., at ages under 40, or 95 mm. hg. at ages over 45, will show a higher mortality than normal.

ULCERATIVE COLITIS AS A COMPLICATION OF ABDOMINAL OPERATIONS*

J. Arnold Bargen, M.D.,
Division of Medicine, The Mayo Clinic,
and
Fred W. Rankin, M.D.,
Division of Surgery, The Mayo Clinic,
Rochester, Minnesota

A DEFINITE or even a likely explanation of the cause of postoperative diarrhea rarely can be given. There are times when the condition becomes intractable. Diligent search of the numerous watery, sometimes lienteric stools, fails to reveal organisms of dysentery, typhoid fever, paratyphoid fever, or of any of the Gram-negative bacteria associated with intestinal disease. Likewise, search for parasites of all kinds proves fruitless. Usually there has been normal postoperative convalescence for the first four to six days, or even for a week, with the usual postoperative rise in temperature with subsequent return to normal and, then without demonstrable other break in the postoperative course, the patient has complained of abdominal cramps and has begun to pass loose stools. At first three to four stools have been passed in twenty-four hours, then gradually the number has increased to many rectal discharges in twenty-four hours, usually watery and mixed with pus. When this stage has been reached, occult blood soon appears, but gross blood in noteworthy quantities rarely is recognized. Occasionally the stools are streaked with blood. The patient gradually fails, he has great difficulty in retaining food or drink, and consequently the intake of calories by mouth is substantially reduced. Moreover, he becomes steadily depleted by the frequent rectal emissions. There may be a subsequent rise in temperature, but there is just as likely to be an afebrile course, or the temperature may even sink to subnormal levels. Failure is progressive, and finally death occurs. At no time since the onset of the diarrhea has there been a suitable opportunity for proctoscopic investigation, nor has the patient's condition been favorable for such a maneuver.

*Submitted for publication March 26, 1930.

The observation of several such cases prompted us to inquire into the frequency of this complication, and twelve cases were found in the necropsy records of The Mayo Clinic in the years 1922 to 1929, inclusive, or an average of a case and a half a year, in a total of approximately 65,683 major abdominal operations (tabulation). Four reports of illustrative cases follow:

Case 1 (Case 2 in the tabulation).—A woman, aged fifty-two years, the wife of a farmer, came to the clinic October 25, 1923, complaining of gastric trouble of thirty-two years' duration. She never had felt well in these thirty-two years, but with her attacks of indigestion her condition was worse. At such times, she had gas, belching, sour stomach, nausea, and a dull, aching pain in the epigastrium an hour after eating. Occasionally there was emesis, but never of blood. The condition gradually had become worse. She had taken many kinds of medicine, with temporary relief. Taking of soda used to relieve her. In the few months preceding her admission to the clinic, she had had three very severe attacks. She had lived on a bland diet for some time.

On admission, the patient's weight, which had been 130 pounds five years before, was 100 pounds. The blood pressure in millimeters of mercury was 94 systolic and 60 diastolic. The numbers of leukocytes and erythrocytes were within normal limits. Roentgenograms of the stomach gave evidence of a gastric ulcer. Examination otherwise gave essentially negative results.

November 5, 1923, knife excision of the ulcer, and posterior gastro-enterostomy was done. About the seventh day after operation intermittent vomiting began. The vomiting was worse after the thirteenth day. It was found that very little was passing through the stomach. The urinary output fell, and the blood urea rose to 126 mg. in each 100 c.c. On the seventeenth postoperative day, jejunostomy was performed. Everything seemed in good condition about the opening made at gastro-enterostomy. There was some angulation of the duodenum, which was adherent to the anterior abdominal wall; this was released. Failure was progressive and the patient died on the fifth day after the jejunostomy.

At necropsy ulcerative colitis, with perforations in the

sigmoid portion of the colon, terminal local peritonitis, and an old, healed duodenal ulcer were found.

Case 2 (Case 3 in the tabulation).—A man, aged fifty-nine years, a farmer, came to the clinic August 19, 1929, with a history of epigastric distress for ten or twelve years. This distress consisted of a feeling of fullness which came between one and two hours after meals, and lasted about an hour. Application of heat would relieve him; taking of food would not. There was some pyrosis. The attacks would be worse in the fall of the year. There had been no visible blood in the stools. The bowels had moved normally.

The patient appeared sallow, and had lost 20 pounds in weight. There was some sense of resistance in the epigastrium. Otherwise examination gave negative results. The numbers of erythrocytes and of leukocytes were within normal limits. Roentgenograms of the stomach gave evidence of an ulcer on the lesser curvature, fairly high in the stomach.

August 24, partial gastrectomy of the posterior Polya type was done, and a perforating ulcer of the stomach was found. For the first three days after operation the patient's condition was good; his maximal temperature was 100.8° F. On the fourth day he had eight stools in twenty-four hours; on the fifth day, eighteen stools, and from then on persisted intractable, continuous diarrhea. The patient had no desire to eat, and refused food. Solution of glucose was given intravenously, and finally nasal feeding was resorted to. He died September 21, from subacute ulcerative colitis, involving the entire colon.

Case 3 (Case 5 in the tabulation).—A man, aged sixty-three years, a farmer, came to the clinic in December, 1928, with a history of attacks of distress in the upper part of the abdomen of eight years' duration, characterized as spells of indigestion. He had hunger pains at bedtime, which were relieved by taking milk and crackers before retiring. During the harvesting season he had been accustomed to eating a heavy meal about 8:00 p. m. and would begin to have a burning type of distress, with much belching, about 2:00 a. m., which was relieved by drinking milk and eating crackers. He would also have distress in the afternoon, particularly after eating a large noonday meal. This would be relieved by eating something, or would continue until the evening meal. In the few years previous to his coming to the clinic the distress had come in cycles, lasting about a month at a time, with intervals of six to nine months of freedom. A few months before admission, the nocturnal distress had become more noticeable. There had been occasional emesis. There never had been any real colic in the upper part of the abdomen, although he recalled that for twenty years he had had some indigestion, but for the first twelve years it had not been as marked as it had been in the last eight years.

General examination revealed that the patient weighed 40 pounds less than what he said he had weighed five months before admission. The only thing of note in the blood count was that leukocytes numbered 12,000 in each cubic millimeter. Analysis of gastric content disclosed total acidity of 26 and free hydrochloric acid of 22 (100 c.c. of gastric content neutralized by 2.6 c.c. and 2.2 c.c., respectively, of tenth-normal sodium hydroxide). By aspiration, 110 c.c. of the test meal was recovered. Roentgenologic study of the gallbladder showed it to be functioning normally, and similar study of the stomach revealed a defect of a duodenal ulcer. The patient was hospitalized and further studies were suggested. Along with the gastric distress, there had been symptoms suggesting gallbladder colic.

Exploration, March 4, 1929, revealed adhesions around the duodenum, biliary cirrhosis, and a choledocholith. Choledocholithotomy and choledochostomy were performed. Convalesence was uneventful and the patient was dismissed from the hospital, March 18. It was noted, however, that on the ninth day of his stay in the hospital he had six loose, watery stools. This was six days before dismissal, although in those six days his stools had continued to be loose.

The patient returned, April 3, stating that his diarrhea had become worse a few days after leaving the hospital and had progressively increased in severity. On admission, the patient looked very ill, had a temperature of 100° F. with some abdominal distention and tympany, and marked tenderness along the line of the colon. The question of an obstructive lesion, with peritonitis, was raised. Failure was very rapid and death followed on the third day after readmission to the hospital. The anatomic diagnosis was acute, severe, ulcerative colitis.

Case 4 (Case 11 in the tabulation).—A woman, aged fifty-six years, came to the clinic March 9, 1927. A diagnosis of pelvic abdominal tumor was made and exploration was undertaken, March 13. Carcinoma of the right ovary, involving the uterus and anterior wall of the sigmoid colon, was found, for which bilateral oöphorectomy and salpingectomy, subtotal abdominal hysterectomy, and resection of a portion of the sigmoid, and colostomy were done. The pathologist reported squamous-cell epithelioma, graded 4. The patient made an uneventful convalescence and was dismissed from the hospital on the twenty-sixth day after operation, with an afebrile temperature and feeling fairly well. The last eighteen days of her stay in the hospital, however, there had been diarrhea, which had reached its maximum five days before dismissal, and the last few days it had seemed to be controlled by paregoric and bismuth. However, after the patient had left the hospital, the diarrhea had continued, and had become steadily worse, so that she returned to the hospital, June 30, four days after dismissal. From then on her condition became progressively worse, and she lost weight rapidly. In spite of the use of tincture of opium, tincture of iodine, paregoric, and other symptomatic agents, her failure was progressive and she died, July 10. The anatomic diagnosis was metastasis to the pelvic and abdominal aortic nodes, ulcerative colitis, graded 3, and pelvic abscess.

COMMENT

An interesting question arises concerning possible etiology of severe fulminating, fatal colitis, and its incidence after operation on the

DATA CONCERNING ULCERATIVE COLITIS AS A COMPLICATION FOLLOWING ABDOMINAL OPERATION

Case	Age, years, and sex	Diagnosis	Surgical procedure	Time of onset of diarrhea, days after operation	Death, days after operation	Cause of death

*Reported in text of article.

upper part of the abdomen. It will be noted that in eight of the twelve cases (tabulation) operation was on the stomach or biliary passages, and in six of these operation was primarily on the stomach. In three of the cases, there were pelvic operations; in only one case was operation primarily on the large intestine, and that in a case of long-standing obstruction. The possibility of the occasional, or frequent, presence of organisms, either in the lumen or the wall of a diseased viscus must be borne in mind. Whether or not similar or closely related organisms occur in peptic, cholecystic and intestinal ulcers is not known. Rosenow,[3,4] frequently has isolated strains of streptococci from peptic ulcers and infected gallbladders, and many workers, including one of us (Bargen[1]), have found a diplostreptococcus in the ulcers of chronic ulcerative colitis. How closely these various organisms are related has not been determined. We have called attention to the occasional existence in the same person of peptic ulcer and chronic ulcerative colitis, and to the subsidence of the symptoms of the former with the treatment of the latter.

Also it should be noted that in 1929 two patients, whose condition clinically was like that of the twelve reported, on empiric grounds were given the specific immune chronic ulcerative colitis antibody solution[2] and recovered.

For those who might consider ulcerative lesions of the colon of this type to be on a metabolic basis, an answer would seem to lie in the rapid course which these cases followed. All of the patients seemed to represent average surgical risks except the one who had intestinal obstruction. True, all but two of the patients were between the ages of fifty and sixty-seven years, but in seven the results of blood counts were negative and in only one patient (case 10) was there noteworthy anemia, the concentration of hemoglobin being 37 per cent (Dare) and erythrocytes numbering 2,540,000 in each cubic millimeter of blood. Most of the patients had lost considerable weight; in case 6 the loss had been 60 pounds; in case 7, 24 pounds; in case 9, 30 pounds; in case 10, 30 pounds, and in case 4, 40 pounds; except for these factors, the preoperative condition of the patients was favorable. Furthermore, none of the patients had been exposed, either before or after operation, to any of the usual bacteria generally recognized as causing dysentery.

It would seem, then, that the causative factor was present at the time of the patient's operation and that postoperatively certain other factors were brought into play to cause the etiologic agent to become active.

SUMMARY AND CONCLUSIONS

Severe postoperative diarrhea, if it is found not to be due to any of the usually recognized causes of dysentery, may be of the type of chronic ulcerative colitis and can justly be treated as such.

As long as the cause remains obscure and the case is fulminating, and therefore adequate means of investigation of the cause are difficult to apply, any measures of combating the condition may be judiciously undertaken. The great value has been demonstrated of specific antibody solution prepared from immune horse serum in cases of chronic ulcerative colitis in which the etiologic agent, apparently, is the diplostreptococcus.[2] It seems reasonable, therefore, to include administration of this antibody solution in the therapeutic measures, or perhaps to think of it as the most effective of them. If the case does not yield promptly to this, ileostomy, with short-circuiting of the fecal stream, may be indicated. This operation has found favor in refractory or complicated cases of bacterial chronic ulcerative colitis and may be a life-saving measure.

PERNICIOUS ANEMIA: AN HISTORICAL SUMMARY WITH ESPECIAL REFERENCE TO THE OCCURRENCE OF FEVER

K. K. Sherwood, M.D.,
Redmond, Washington
and
W. R. Humphrey, M.D., F.A.C.S.,
Stillwater, Minnesota

THE late Charles Lyman Greene[1] has defined Addisonian Pernicious Anemia as follows: "This is a primary anemia, probably invariably fatal, progressing slowly by remission and relapse, characterized by hemolysis and perverted hemogenesis associated with progressive and ultimately fatal extreme diminution in the number of erythrocytes in the circulating blood, the appearance of large numbers of immature red blood cells and a marked reduction in the hemoglobin with a relatively high individual cell hemoglobin content which results in a high color index." This gives a very clear idea of the anemia side of the disease, but we wish to emphasize in this paper that Addison's anemia consists not only of the anemia but of certain changes in the gastro-intestinal tract, and usually in the central nervous system. We believe that Dr. Greene's definition could be rendered more inclusive if it is specified that the presence of an achlorhydria is an essential invariable finding, in addition to which there is usually anatomical evidence of the existence of a glossitis. Furthermore, evidence at hand is conclusive that at least 80 per cent of the sufferers with this disease present signs and symptoms indicative of degenerative changes in the posterior and lateral columns of the spinal cord.

HISTORY

Osler, we believe, is credited with the statement, "Know syphilis and you know medicine." While perhaps not quite so true with regard to pernicious anemia, one can truly say, "Know pernicious anemia and know more medicine." The progress of our gain in knowledge concerning pernicious anemia has been very slow with the exception of two periods, that of the present and that from 1870 to 1880.

Coombe[2] of Edinburgh was the first to recognize the existence of this peculiar anemia as an individual disease, and it is very interesting to read that this canny Scot viewed it as "a peculiar disease, which will doubtless be viewed in different appellations." His prophecy has certainly been many times fulfilled. The next case to be recorded in the literature is that of Channing[3] of Boston, edited in 1842 in the New England Quarterly Medical Journal. There is very good evidence that the existence of an anemia of unknown cause and pathology, invariably fatal, had been recognized by the Boston clinicians for ten or fifteen years prior to this. Unfortunately for the credit of American medicine, however, they failed to differentiate it either from the anemia subsequent to multiple pregnancies or from the anemia of pregnancy. When we consider, however, that the so-called primary, or severe anemia of pregnancy is not as yet clearly differentiated from Addisonian anemia we need feel no especial chagrin at their failure.

These remain the two instances of this disease in the literature up to the time that Addison[4] first gave his now famous dissertation upon the disease of the suprarenal bodies in 1849. At this time, while recognizing that some of his cases did not have demonstrable pathology of these organs, it was not till his later publication[5] in 1855 that he clearly differentiated the two conditions, the one of the suprarenal bodies being now called Addison's disease, and the other idiopathic anemia being referred to as Addison's anemia.* Apparently, as is common in medical circles, attention was paid to the disease with manifest pathology but it is not until 1871 that we again find this idiopathic anemia receiving its share of the limelight.

In this period of twenty years I am able to find only one article of any detail, that of Habershon,[6] published in the Lancet of 1863. In a lecture on anemias he reported, with other cases,

*Attention should be called to the description of a fatal case of anemia corresponding in type to that described by Addison, published by Barclay[7] in 1851.

that of a woman, aged 40, in whom the disease had a gradual onset with weakness, a yellowish pallor, and with gastro-intestinal symptoms of pain, occasional nausea and emesis, alternating constipation and diarrhea, but, withal, not accompanied with cachectic wasting. The white blood cells were not increased in number. The postmortem examination was negative except for a fatty degeneration of the heart, especially prominent in the walls of the left ventricle. The state of the knowledge of this affection in 1870 seems to me to be well represented in Austin Flint's Principles and Practice of Medicine[8] (1868). He stated: "Addison has described cases of anemia occurring without any obvious causation, accompanied by general debility which progressively increases, at length ending fatally, without appreciable lesions of any of the vital organs. Cases of this kind are occasionally met with, especially in hospital practice. Addison distinguishes them as cases of 'idiopathic fatal anemia.' In a certain proportion of these cases the surface of the body, to a greater or a lesser extent, assumes a dark discoloration or a bronzed appearance, and in several successive cases the suprarenal capsules were found to be more or less disorganized. Addison inferred from these facts a pathological connection between disease of the suprarenal capsules and the bronzed hue of the skin. Clinical observation, however, shows that the two events are not uniformly associated." Certainly there remained much to be done, before the idiopathic anemia was to be firmly founded as a clinical entity.

With the increasing prominence of the Teutonic medical centers we find pernicious anemia re-discovered. The first paper on the subject then was that of Gusserow,[9] in Zurich. He reported five cases of severe anemia in pregnancy or the puerperium. The true value of these cases is doubtful. But in the following year, a colleague of his, Biermer,[10] published the paper which gave the impetus to the diagnosis and investigation of this disease. He claimed to have seen fifteen cases in five years, which at once placed the disease among the less common, instead of among the little known rarities. While one may doubt the authenticity of several of his cases, one can not doubt that, aside from the neurological aspect, he clearly recognized all the symptoms of Addisonian anemia. To quote from his paper in regard to the etiology: "Miserly and improper food, bad rooms, dehydration, especially protracted diarrhea, foster the progress of the disease and cause it." Such a viewpoint expressed today would classify the disease as a deficiency disorder. His division of the symptoms and their interpretation is no less modern. He classified them into eight groups: "1. Anemia-hydremic phenomena: great pallor, poor nutrition, but no atrophy of the fat cushions such as occurs in carcinoma and phthisis. Often a yellowish white facial color without jaundice. In far advanced cases, moderate edema-like puffiness of the lower eyelids, and feet and hands, occasionally ascites. 2. The corresponding anemia nerve symptoms: weakness, faintness, palpitation of the heart, etc. 3. Digestive disturbances, the sequences of the fatal loss of appetite: poor digestion, sometimes the feeling of pressure in the stomach; very often intermittent diarrhea. 4. Circulatory symptoms—murmurs in the heart and blood vessels, very often so loud that one must question the existence of a cardiac defect. The murmurs are systolic, though occasionally there is a diastolic in addition without a degeneration of the valve being found at post-mortem: at the base the systolic murmur is rougher than over the ventricle, where it is more blowing. . . . The heart action is as a rule hastened, and the heart sounds diffuse, undulating and not vigorous. 5. Fever is uncertain; however, it is observed transitorily in nearly all cases. . . . Distinctly local basis for the fever cannot be found. 6. The retinal hemorrhages are interesting because they are almost constant. 7. Occasionally there were cutaneous hemorrhages, small petechia. Hematuria and epistaxis are occasionally observed, albuminuria only exceptionally. 8. On the contrary, capillary hemorrhages in the brain, on the arachnoid side of the dura, and in the pia, were found in several cases without characteristic symptoms during life. . . . All cases ended in death, with one exception, which was slightly improved." For a clinical description of the appearance of the patient, this could be regarded as entirely up to date with the exception of the neurological findings and the glossitis. At necropsy Biermer found only a moderate fatty degeneration of the heart, especially under the endocardium lining the left ventricle, and what he termed "fatty degeneration of the capillaries" by which he explained the capillary hemorrhages throughout the

body. Why this paper, which is in reality very short, brought the disease into general notice and gave the impetus for the great increase of knowledge which came about in the next ten years, is unexplained. That is just what happened, however, especially in Germany, where the disease is known as Biermer's anemia, and, we believe, justly.

Two years later, Quincke's article[11] appeared, and contained the first glimmering of knowledge concerning the pathological physiology of the disease. By the ferrocyanide test, he was able to demonstrate, grossly and microscopically, the presence of a substance giving the iron reaction in the liver, kidneys, and pancreas. This he verified by chemical analysis, which showed conclusively that there was an increase of iron. Quincke failed to grasp the entire importance of this, which we now know under the name of hemosiderosis, for he thought that possibly this storage of iron could be accounted for on the basis of that found in the medicine that had been administered. In the same year, 1874, Immerman[12] published an extensive dissertation on the subject, in which, however, he added nothing new. Eichhorst[13] in Leipzig in 1874 and again in 1884 was the first to call attention to the peculiar shape of the red blood cells in what he called Biermer's anemia. We in America should be proud that the year 1875 saw the publication of an extensive review of this disease by Pepper,[14] and to him should belong the credit of first clearly describing the replacement of the yellow marrow of the long bones by red marrow consisting of distinctly blood forming elements. He was also the first to mention arsenic in the treatment of the malady. Cohnheim[15] in Germany in the following year confirmed, independently of Pepper, the replacement of the yellow by red marrow, as did Lepert[16] in Paris. The year 1877 was notable for the contribution of Scotland, in the form of a case report by Bramwell[17] of Edinburgh, in which for the first time the presence of nucleated red cells was recognized, clearly described, and well illustrated. Previous to this, while changes in shape had been recognized as common to this condition, nucleated erythrocytes had never been described. Bramwell also brought before the English and continental physicians the value of arsenic in this malady, since the two cases in which he used it recovered. Bramwell possessed true Scottish caution, however, for we find him making this statement, "Although the results were all that could be wished for, I would not for a moment have it supposed that arsenic will be found a specific for this disease."

While such rapid strides were being made in the understanding of blood conditions, gastroenterology had begun to develop. In 1870, we find that Samuel Fenwick[18] had reported a case of primary gastric atrophy. Upon reading his case report, one finds that he was in reality describing pernicious anemia, and that he had most beautifully demonstrated the existence of achylia by experimental means. We can do no better than quote his remarks: "It is well known that an infusion of the gastric mucous membrane when mixed with dilute hydrochloric acid will dissolve albuminous substances; and I have found, by numerous experiments, that one ounce of such an infusion will on the average digest four grains of hard-boiled white of egg. I carefully scraped off the mucous membrane from the splenic and middle regions of the stomach in the preceding case, and infused it in two ounces of distilled water, along with half a dram of dilute hydrochloric acid for twelve hours. A cube of hard boiled white of egg, fifteen grains in weight, was then digested for nine hours at blood heat, but at the end of this period, the albumin had not lost in weight, and the only change produced was a slight softening on its surface. This experiment, therefore, confirmed the conclusion drawn from the microscopical examination, that the gland-structure of the stomach had been so seriously diseased that it could not have been capable of performing its functions during life." Austin Flint[19] of Philadelphia in the following year reviewed Fenwick's paper and added four cases of his own, all fairly typical of Addisonian anemia. In these cases he followed Fenwick's lead and diagnosed primary gastrict atrophy. Fenwick[20] in 1877 reopened the subject with a paper in which were reported seven cases, four with necropsy. These were all typical of Addisonian anemia, and he seems to have been aware at least of the similarity; nevertheless he attributed the accompanying anemia, perhaps correctly, to the gastric glandular atrophy which he had so beautifully demonstrated.

Thus the first great period of activity in research upon this subject was brought to a close with the appearance early in the 80's of two ex-

haustive reviews of the subject in English, the first by Coupland[21] in 1881, and the second by Pye-Smith[22] in the following year. We believe the two are equally exhaustive and reliable, but we find that the second is readable, whereas the one by Coupland is written in a style both difficult to follow, and not clear as to points of emphasis. The first point to impress the American reader in both articles is that the British ire had been aroused at Biermer's claim to have discovered the disease, and both authors wrote insistently and at length on the priority of Coomb and Addison. Coupland tried to incorporate pernicious anemia as a special kind of chlorosis, but seems to us to have failed, most miserably. Pye-Smith was thoroughly imbued with Guy's hospital spirit, and would permit no one to usurp Addison's priority in the description of a new clinical entity. Both papers admirably summed up the knowledge to date.

The period from 1880 to 1926 was one devoted to the proof and amplification of the signs and morbid changes observed in the era preceding it. It was in this period that we had the development of the aniline dyes by Ehrlich,[23] with its corollary, a great advance in the knowledge of cellular detail. By this means we not only had the work of Eichhorst and Bramwell confirmed, but we had the recognition and the anatomical description of the two types of erythrocytic development, i.e., the adult normoblastic one and the embryonic or pathologic megaloblastic type. It was in this same period, also, that it was conclusively demonstrated that megalocytes and megaloblasts are only found in primary anemia. Following this came the work of Price-Jones,[24] another Guy's hospital enthusiast, who measured the size of the red cells in normal individuals and in persons suffering from the various types of anemia. By this method, he gave us another diagnostic criterion in Addisonian anemia. He found it to be pathognomonic of this condition for the red cells to show two distinct variations in size from that of normal blood, or that of blood from the other anemias. The first and most important is that the average diameter, instead of being 7.5 micra as it is with normal individuals, or less as it is with hemolytic jaundice, is increased to 8.5 or even 9.5 micra. This is certainly a well marked difference. The second pathognomonic variation that he observed was in the range of the size of the cells; whereas in normal blood the size may run from 6.5 to 8.5 micra, in pernicious anemia a range from 4.5 to even 11 or 12 micra is the rule. This does not occur in any other form of anemia.

Along with the increase in our knowledge of the histopathology of the blood, we find occurring an increase of interest in the study of the bone marrow changes. Beginning with a paper in the 80's by Osler and Gardner[25] various observers[26] noticed the distribution and the appearances of the red marrow, till we have in a paper by Peabody,[27] of Boston, the culmination of such studies. He and his associates in Boston developed a technic in which, by means of local anesthesia, they trephined through the shaft of the tibia and curretted out a small portion of the marrow for histological examination. The value of this lay in the reporting of the condition of the marrow during life and not after the person succumbed to the disease; thus he was enabled to get marrow from all stages of relapses and remissions. He stated that from their necropsy observations they believed that the replacement of the yellow by red marrow took place first in the bones of the trunk, next in the femurs and humeri, and lastly in the legs and forearms; while in a remission the opposite was true, the red marrow disappeared first from the bones most distal from the trunk, and only in a complete remission were absent from the vertebræ, ribs, etc. Hence, a biopsy from the tibia gave the most sensitive index of the stage of the disease. He found that during a relapse the fat practically disappeared to be replaced by hemopoietic tissue, consisting largely of columns and cords of megakaryocytes, some of the myeloid series, and a few of the normoblastic type. Mitoses were rare in the latter, occasionally found in the myelocytes but exceedingly numerous among the megakaryocytes. The hyperplasia was so extensive that the venous sinusoids were practically collapsed. Their outlines were distinguished only by the aid of the hemosiderin granules contained in their walls. In the beginning of a remission there was a distinct difference in the picture; crowding was not so intense, and the preponderance of mitoses had shifted from that of the megakaryocytic series to that of the normoblasts. When a remission was well established, the fat cells had returned and occupied the larger part of the space normally theirs. Even when the remission was practically

complete, however, cords of megakaryocytes existed among the fat cells, though mitotic figures among them were conspicuous by their absence. The conclusion to be reached from this seemed to be that, though the organism had largely returned to the normal method of blood manufacture, the possibility of reversion to pathologic type was ever present.

Of the two additional morbid changes that have been described since 1880, that of the central nervous system holds the priority. Lichtheim[28] in 1887 described changes in the posterior and lateral columns of the spinal cord in three cases of severe anemia. This was shortly followed by three additional cases described by Minnich.[29] Later the spinal cords of twelve additional cases of Addisonian anemia were examined by Minnich, and, though they had not complained of neurological disturbances during life, the same type of change, though not to the same extent, was found to occur in their cords. In 1895, Bowman[31] collected the literature and with his own case was able to find eleven Addisonian anemia patients who had complained of distinctly neurological symptoms during life. Bowman's description of the gross changes is as accurate today as it was when he wrote it, thirty years ago. "In every instance there was degeneration in the posterior columns, most marked in Goll's tract, but also involving more or less of the posterior-external columns; but in the latter case leaving a strip of undegenerated white matter on the inner surface of the posterior gray cornu. The posterior roots and Lissauer's tract were invariably intact. In four instances (66 per cent) the lateral columns were also affected, the degeneration being situated chiefly in the outer and posterior portion, and in three of these cases similar changes were also observed in the anterior columns, chiefly in the situation of the direct pyramidal tracts."

Since that time, neurological signs have been increasingly looked for, so that now in at least 80 per cent of the cases they are reported as being present.[31,32] The location of maximum areas of destruction as occurring in the lower cervical and upper thoracic levels of the cord have since this time been abundantly confirmed. The best description[33] that we have been able to find of the histology of the process is as follows: "The microscopical details are typical in that they begin around and spread from the vessels . . . Beginning as small lesions, these latter coalesce in such a manner as to give the cord a cribriform appearance." In 1923, Woltman[32] of the Mayo Clinic gave a paper on the mental changes found in pernicious anemia. He agreed with Barrett[34] that lesions similar to those described in the cord did occur in the brain. Furthermore, Woltman found that 4 per cent of the cases of pernicious anemia that came to the Mayo Clinic had a more or less marked mental disorder and he expressed himself as agreeing with the findings of others in smaller series, namely that these patients were especially prone to ". . . apathy, indolence, decreased mental work, loss of memory, delirium, shallow confusion, stupid indifference to surroundings, to external impressions and to the disease itself; instability, shallow confusion, with impairment of ideas of time and place, abeyance of the mind, loss of inhibition, peevishness, gradual mental deterioration, varied by control, good temper, and an angelic disposition for longer or shorter intervals; somnolence, with a tendency on being aroused to exhibit a certain degree of mental confusion, particularly to surroundings, which may manifest itself in a delirium of a low quiet type, a continuance of the dream state which the patients can not shake off on being aroused, and which usually subsides spontaneously on further stimulation." With regard to the etiology and prognosis in these mental cases, the same author expressed himself as follows: "Why it is that some patients develop psychosis and others do not, is a hard question to answer. It may be that constitutional factors play the deciding part; this was very evident in some of our cases, but by no means in all . . . It is usually said that the mental disturbances proceed pari passu with the intensity of the anemia . . . but it does not invariably hold for the cases in which the more marked mental disturbances are exhibited." Thus we see that there is a process of gradual disintegration in both the spinal cord and brain of some of the sufferers from this malady.

Turning now to the gastro-intestinal side of this disease, we find the second of the new facts discovered in this period of slow ramification of knowledge. This consisted of the description in 1888 by William Hunter[35] of a peculiar form of glossitis occurring in patients suffering from Addisonian anemia. In 1903 he further ampli-

fied this, in the report[36] of 25 cases. This article he devoted to two objects: first, a defense of the original view of Addison concerning the disease; and, second, its etiology. From what we read about him, William Hunter was of a somewhat fiery disposition, very prone to take sides, and argue violently in favor of his convictions. Fully half of this article was filled with the lauding of Addison and his British contemporaries and the satirizing of the viewpoints of Biermer, Eichhorst, and especially Quincke. To us, the final touch of irony is that the especial fault that he most deeply abhorred in them, namely the assigning of a cause to Addisonian anemia, he himself committed in the second section of his paper. His opinion can be best expressed in his own words: "In all the cases observed during life, 25 in number, and in the cases, 7 in number, in which postmortem examinations were obtained, I found certain infective lesions in the mouth, tongue, stomach, or intestines—either singly or associated with each other. These were of two classes: 1, a special form of glossitis (in every case); 2, septic lesions, viz. (A) a preceding or existing 'oral sepsis' (24 cases); (B) 'septic gastritis,' the condition I described (1900) as a common result of the long continued oral sepsis, causing finally gastric atrophy (more or less in every case and most intense in 3 cases); (C) 'septic enteritis,' e.g., a croupous enteritis, patches of congestion and catarrh, follicular enlargement, and patchy colitis (3 cases). With regard to these, the point to be emphasized now in view of the significance I shall subsequently attach to them is: in no cases were these lesions either in anatomical character or severity sufficient of themselves to originate the intense anemia by any interference with nutrition they may have been capable of producing." And again under special etiology, "There are two classes of lesions which I consider of importance in this relation—1, a hemolysis of special degree and character, well shown by the analyses in the present series of seven cases; and, 2, a glossitis, observed in every case, having the peculiar relation to the onset of the anemia, and clinical character suggestive of its being of an infective nature, described by me in 1900. Histological examination in seven cases shows that it has even more striking pathological features, and in all three cases bacteriologically examined, these are associated with, and presumably dependent upon, a deep seated pure streptococcal infection of the substance of the tongue." One wishes that he had been more detailed in descriptions of this glossitis, but he evidently was describing the same phenomenon that Dr. Schneider[37] of Minneapolis had recently so beautifully shown, namely that beneath the mucosa of the reddened areas on the tongue in active cases of pernicious anemia, there can be seen and isolated pure colonies of streptococci viridans.

The percentage of pernicious anemia cases having achylia gastrica had risen steadily with our increase in knowledge of this disease. From statements made in 1890 that it was said to occur frequently, we find that in 1910 achylia occurred in over 90 per cent of the cases; while at the present time the diagnosis of Addisonian pernicious anemia can not be made without the proven absence of hydrochloric acid from the stomach.[31,39] Along with the increasing importance of this achylia, there has been developing a more and more active discussion as to its duration. At the present time it is generally conceded that it exists prior to the development of the disease, but as to how long, there are two very distinct schools. Hurst[31] in England strongly affirmed the hereditary origin of this gastric malfunction and pointed to the several pernicious anemia families that could be found in literature, and to the fact that the blood relatives of pernicious anemia patients show the absence of free hydrochloric acid from the stomach much more frequently than does the population as a whole. Faber[39] in Copenhagen was equally emphatic, however, in stating that the origin of this achylia was an infection, and he pointed out that in all these cases of achylia there could be found, by careful search of the past history of the patients, a story of an acute gastric-intestinal infection at some time in their lives. The correctness of either opinion is probably of more academic than practical importance.

Along with the increasing knowledge of the gastric secretions, there has been developed since 1880 the beginning of the chemistry of bile and hemoglobin constituents in the feces and serum. Eppinger[40] and Schneider[41] found that in Addisonian anemia the total amount of urobilin found in the feces for twenty-four hours was materially increased above that of the normal. Schneider[42] carried this work further and has attempted to show an increase of urobilin in the duodenal con-

tents. While this is the only thing discovered that is strictly new, yet it has rendered previously observed facts into mathematical terms and perhaps cast some physiological light on the descriptions of the yellow color of the blood plasma which was noticed and remarked upon by the original writers on pernicious anemia. Foremost among investigators in this field of serum chemistry had been Van den Bergh,[43] whose test for bile pigment in the blood is now known to every junior medical student. He found that in relapses of pernicious anemia there was a delayed positive reaction of the serum. This is generally interpreted as meaning that there is in the blood an increase of bile pigments, which have not been excreted by the liver, in other words a mild degree of non-obstructive or toxic jaundice. The explanation offered for the fact that the reaction takes place only with the addition of alcohol to the serum, and that the color of the pernicious anemia patients is distinctly different from that of the ordinary jaundiced ones, is that in the excretion of these blood pigments by the liver into the bile they are slightly changed in chemical structure. The same increase in the pigment matter of the serum can be shown by the icterus index. Thus the period of slow increase in knowledge is brought to a close and we have, in 1926, Addisonian anemia pictured as an idiopathic anemia characterized by remissions, a high color index, a wide variation in the size of the red blood cells, but on the whole distinctly larger cells than normal, a quantitative measurement of the yellowness of the blood serum as expressed by the Van den Bergh and the icterus index. We have it demonstrated that the majority of cases have at some time a glossitis, from which can be isolated pure cultures of streptococci, that almost if not invariably there is an absolute achlorhydria; and that there will be signs of degenerative changes in the central nervous system in the vast majority of cases.

We come now to the second period of rapid development in our knowledge of pernicious anemia. This began with the publication by Minot and Murphy[44] of a paper dealing with the therapeutic effects of a vitamin-rich diet, containing a large amount of fresh liver. Since Bramwell's description[17] of the therapeutic effect of arsenic in 1877, there had been little progress in the treatment of this disease. Transfusion had become a simpler and a safer procedure, but at best, it seemed only to hasten the spontaneous remissions, and did not seem of great value in the severest cases when they were on the down hill grade. In the ten years preceding this paper, various dyes had been tried with more or less indifferent success. Two Iowa physicians[45,46] have reported upon the favorable effect of intravenous mercurochrome; additional reports as to its value we have been unable to find, though numerous cases of other diseases in which it has been used with disastrous results abound. Ultra-violet light has had its advocates[41,49] some using it alone, others with one of the aniline dyes (eosin or gentian violet) as a sensitizer. A review of the incidence of relapse in this disease in relation to the time of the year did not give any proof of the lack of ultra-violet being a factor in the causing of the downward trend.[50,51] Some investigators, basing their hopes on the origin of the disease in gastro-intestinal infection, have tried to inhibit the growth of bacteria in this region. The simplest of the procedures with this in view was that advocated by Hurst[31] of Guy's hospital, who believed in large doses of dilute hydrochloric acid, given at least once a day on an empty stomach. In this country, prior to the liver regime, acriflavine and gentian violet were frequently given.[52] Favorable results have not been striking, to say the least.

Various surgical procedures have been tried in the treatment of this disease. Hartmann[53] and Moynihan[54] have both observed the development of an anemia corresponding to Addisonian anemia in all its characteristics following the complete removal of the stomach; the significance of this they have not attempted to interpret. On the theory that the disease is due to an increased blood destruction, splenectomy has been resorted to. Giffin and Szlapaka[55] reported a series of fifty cases in 1920. They came to the conclusion that splenectomy would bring about the beginning of a remission in nearly all cases, and that in 20 per cent it would lengthen the duration of life. Wm. Mayo[56] expressed himself as follows concerning this procedure, in 1925: "In this group [pernicious anemia] there were 62 cases and 4 deaths. Again it is difficult to estimate just how much good splenectomy has done. Immediate improvement practically always oc-

curred. Some of the patients have been in good condition and able to work for over five years. That there is a small group of atypical cases, that are as yet classified as pernicious anemia, and in which great benefit will be derived from splenectomy, there can be no doubt. Generally speaking the younger the case and the shorter the duration of the disease, the better the prognosis." Much more interesting are the results obtained by ileostomy. Dixon, Burns and Giffon[57] have reported six cases in which this procedure had been used, and have summarized the foreign literature. Two of their cases died from diseases other than pernicious anemia, two had a return of the anemia, while two remained well. They and other investigators have found that the cases that stayed free of the recurrence are those in which the terminal ileum lost its colonic type of bacteria and reverted to the normal following operation. This is certainly very interesting, though not at all conclusive, and supplies a fact upon which to base the belief that the disease is a toxic syndrome produced by bacteria in the intestines.

In connection with the theories of the toxic or bacterial origin of this disease, the experiments of Torrey and Kahn[58] should certainly be mentioned. They found that the injection of B. Welchii toxin into the tibial marrow of rabbits and monkeys gave a chronic, persistent, often fatal, anemia, characterized by a blood picture similar, at least, to that of human pernicious anemia. The intravenous injection of this same toxin was not accompanied by more than a transitory anemia.

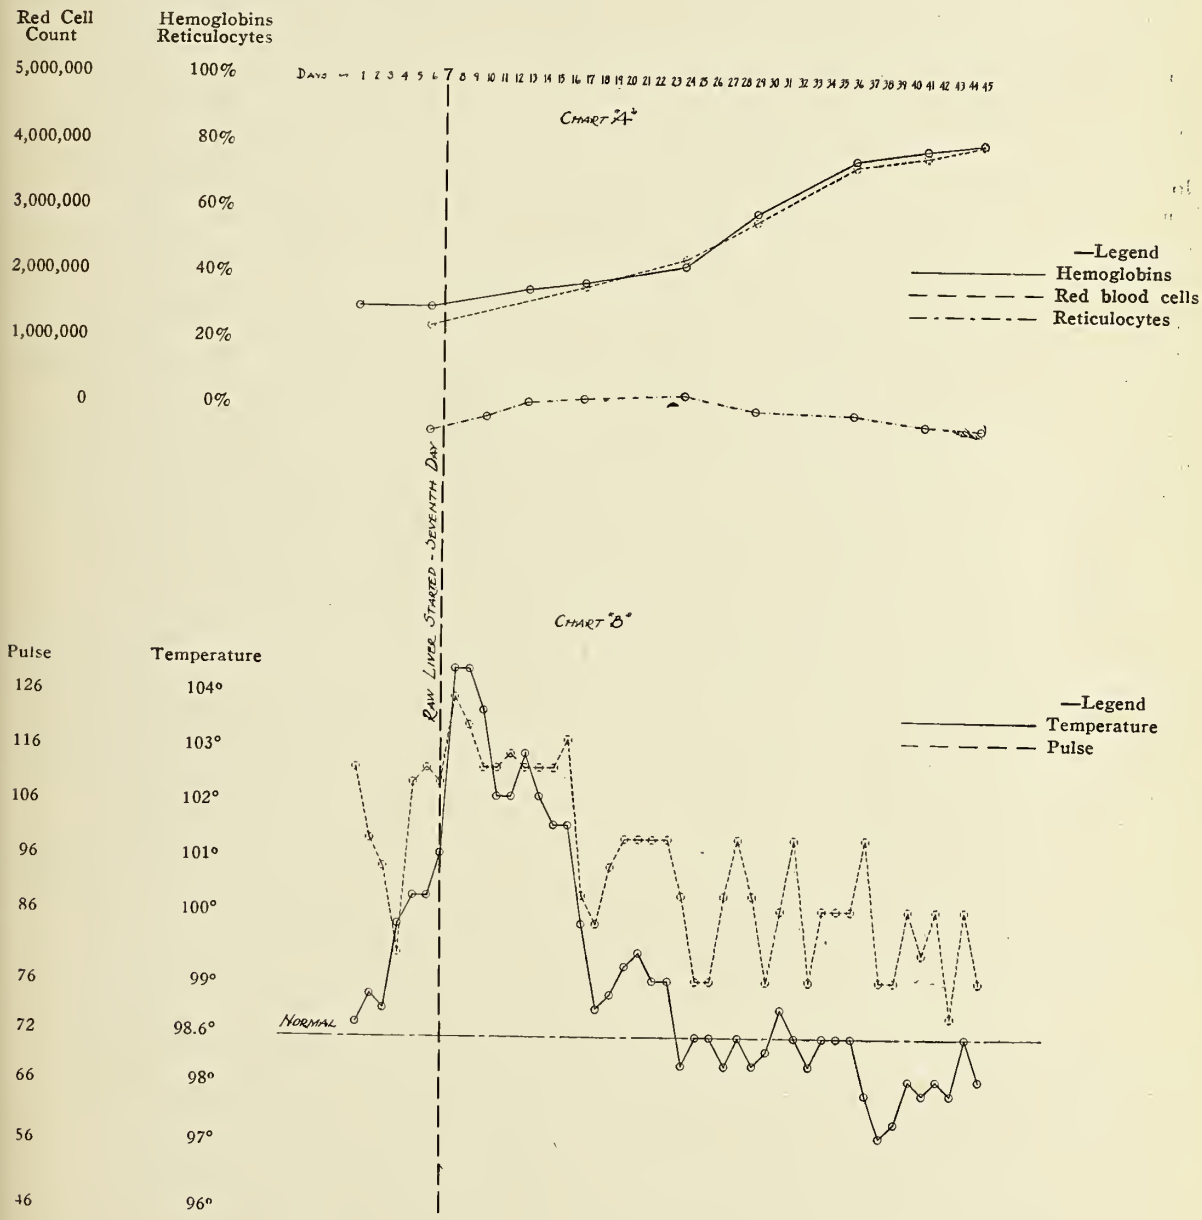
Murphy and Minot[44] adopted a diet in 1926 which contained a high vitamin content and a large amount of liver. They felt that possibly avitaminosis had something to do with the production of the anemia, and in their choice of foods they followed very closely the suggestions of Whipple. Whipple,[59, 60, 61] who had been very much interested in the study of anemia in dogs for a period of years, observed that his animals that were kept anemic by bleeding would regenerate blood faster if they were on a diet containing a large amount of liver and kidney. On the other hand, Koesler[62] and his co-workers had been able to produce in aimals an anemia that resembled pernicious anemia in its blood features by the withholding of Vitamin A. When this element was supplied there occurred a marked period of blood regeneration. Concerning their diet as used in 1926, Minot and Murphy[44] state: "That the dietetic treatment is of more importance than hitherto generally recognized. The diet we have selected is one composed especially of foods rich in complete protein and iron, particularly liver, and containing an abundance of fruits and fresh vegetables, and relatively low in fat, ... Following the diet, all patients showed a prompt, rapid, and distinct remission of their anemia, coincident with at least a rather marked symptomatic improvement, except for pronounced disorders due to spinal cord degeneration." Since that time the medical world has devoted itself to the feeding of liver, and the watching of what has happened. It seems regretable that there has been no further follow-up of the work on ileostomy, or on the ultra-violet light treatment.

Investigation into what happens and why, in these cases, is intimately bound up with a class of red cells known as the reticulocytes. These are red cells in which the supporting stroma can be brought out by means of staining with cresyl blue. The method that we have used is the mixing of a drop of blood with a solution of this dye, then spreading the drop in the ordinary way to make a smear. After drying rapidly, this is stained with Wright's blood stain. The reticulocytes show themselves as red cells plus a network, more or less incomplete, of blue staining material. The work of Cooke[63] has proven quite conclusively, we believe, that this is an indication of immaturity, consisting probably of an increased permeability of the lipoid envelope encasing the cell. These reticulocytes are present in normal blood to the extent of about .5 per cent of the red cells. In conditions of increased blood production, they rise to 3 or 4 per cent, which is the usual figure that is obtained in Addisonian anemia prior to the beginning of liver therapy. Observers[64,68] agree, however, that within three to ten days after the beginning of adequate liver feeding, there is a rapid rise in the number of circulating reticulocytes. Only two manifestations of successful therapy can be noted before this rise: within a day or two after liver is begun, the patient begins to feel better, noticing that his languor is less,

and that his appetite is increasing. The second manifestation is even more striking. As we have said, in this disease, there is an increase of the bile pigments of the blood; just before the reticulocytes begin to rise, this rapidly drops to the normal. No one has an explanation that accounts for this phenomenon. The reticulocyte response beginning in the first week rapidly increases until the third week. The height to which the count of these cells rises seems to be quite definitely inversely proportional to the red cell count prior to the beginning of treatment.[64] Increase of the red cells and the hemoglobin value rise more slowly and do not reach their peak until a month or more after that of the reticulocytes. The color index at the same time becomes lower, which is, of course, due to the return of the normal sized red cells. The influence of liver therapy on the nervous and the gastrointestinal findings is certainly not marked. We know of only one case in which the hydrochloric acid was supposed to have returned and of only one case in which gross neurological findings have changed for the better.[70] It is to be expected that the paresthesias will improve; all authors agree on this, especially emphasizing that it may not be marked until after the blood count is well over four million. Rubert[69] is the only person who has so far recorded the disappearance of a gross neurological syndrome; and these occasionally disappeared prior to liver therapy. The junior author well remembers a case (No. 39345 University of Minnesota Hospital) that he saw while an intern, in which the patient had been seen and diagnosed as a well advanced case of posterior-lateral degeneration seven years before he was admitted to the medical service of the University of Minnesota Hospital, suffering from a high grade anemia, which was completely typical of that described by Addison. Careful neurological examination at this time, however, showed nothing more than a very mimimal disturbance in vibration sense.

The effect of liver seems to be almost specific for this one disease. Only two other conditions give a response at all comparable and they are the pernicious anemia of pregnancy, and sprue.[70] In these occasionally the reticulocytes will give a rise that is comparable to that which occurs in Addisonian anemia. In all other forms of anemia, the benefit of liver and kidney feeding is that of a non-specific; that is, any other equally iron-rich food would give an exactly similar rise in the hemoglobin values, and there is no accompanying response of the reticulocytes.

Work has been done on what it is in liver that gives this specific response, and the Eli Lilly Manufacturing Company was the first to perfect a potent extract. West,[71] of New York, who has done so much work on the problem of isolating the active constituent, believes that it is a polypeptide. The finding of an almost specific for pernicious anemia, in a substance that is certainly in the same general class of compounds as vitamins, has thrown the question of etiology of the disease again into the guessing contest. There are at the present time two opposing views. The newer view points to the therapeutic effect of liver, and indicates that we are dealing with a deficiency disease. Means and Richardson,[72] for instance, make the following statement: "It would seem fair to assume, in view of the new facts, that pernicious anemia is in some sense or other a deficiency disease, rather than an infectious, toxic, or neoplastic one . . . .; but it seems doubtful that pernicious anemia bears more than a slight resemblance to any of the other deficiencies with which we are now familiar. It is not a simple avitaminosis. Thus far it (the active principle) has not been found in plants, and unless vegetable sources are subsequently found, we are forced to conclude that some animals, at least all such as can live strictly vegetarian existences, are capable of carrying out its synthesis." And as to the significance of the pre-existing achylia, they summarize the work of Castle[73] as follows: "Working on this hypothesis [that the achylia had something to do with the genesis of the disease] he [Castle] showed that response similar to that obtained from feeding liver could be elicited in the majority of patients with pernicious anemia studied, by the feeding of skeletal muscle previously digested in a normal human stomach." Thus we have both sides recognizing the importance of the achylia, but upholders of the infectious or toxic theory have much in their favor. They quote widely the work of Macht,[74] which is perhaps best summarized in his own words: "1, Phy-



topharmacologic examination (consisting of comparing the rates of growth of seedlings in normal and anemic serum) of the blood serum from pernicious anemia shows that such serum is very toxic for plant proptoplasm, and thus suggests a toxin as the etiologic factor in this disease. 2, This phytotoxic property of pernicious anemia serum is not shown by blood serum specimens from various other blood diseases and is in this way useful in the differential diagnoses. 3, Irradiation of the pernicious anemia serum with ultra-violet rays in quartz containers renders the serum less toxic, and that effect can be increased by the addition of certain photodynamic sensitizers, e.g., eosin. 4, No treatment entirely destroys this toxicity, though both the liver and the light treatments decrease it." The fallacy in this chain of reasoning is, of course, that while it shows the presence of toxic substance, it does not differentiate whether this is the cause of the disease or one of the results of it. The most conclusive work, or at least that which it is going to be hardest to overthrow, is the work of Hunter[35] and Schneider[37] with the finding of streptococci beneath the mucosa of the tongue. The experimental work on the production of Addisonian-like forms of anemia in lower animals by means of the toxic products from various bacteria (streptococci and bacillus of Welch[75, 76]) does not seem to us conclusive. Even less well founded are the theories that the anemia is produced by bacteria in the stomach and duodenum (especial prominence has been given to the streptococcus longus[31] in this connection).

Thus, at the present time, we can say that pernicious anemia is a high grade state of anemia, characterized by abnormal findings in three of the great functional units of the body, to wit: first in the blood, where the most characteristic things are the anemia, the increase in size of the individual red cells with the consequent high color index, the replacement of the yellow marrow by red, embryonic, hemopoietic cells, and in the reticulocyte response to liver therapy. In the gastro-intestinal tract we have constantly a preexisting achylia and a peculiar form of glossitis that develops at some time during the disease. In the central nervous system we have perivascular areas of degeneration in the posterior and lateral columns of the cord, and less frequently in the brain.

TEMPERATURE CHANGES

It has long been a mootable question as to whether the presence of a severe anemia will of itself give rise to temperature. It is exceedingly hard to determine this. Practically all temperature in high grade anemia can be laid to the existence of an infection within the organism. Hence, to separate the role of infection and anemia in the causation of pyrexia is almost impossible. In primary anemia, the one anemia in which infection may not play a role, it has been long recognized that a temperature of a totally irregular type and course is characteristically present. This fact was first noticed by Biermer,[10] who differentiated it from the fevers of typhoid, typhus, and malaria by its extreme irregularity. He attempted to find an anatomical basis for it, looking especially to the occurrence of hemorrhages to coincide with the peaks of the temperature curve. In this, however, he was unsuccessful. All observers since his time have noted the temperature, and, according to their views as to the cause of this disease, the temperature was explained either on the basis of a toxemia or by analogy to the severe luetic anemias. They pointed to the temperature as a manifestation of the degree of anemia. Hunter, in the 80's and 90's, used the presence of a temperature as a strong argument in favor of the infectious origin of this disease. All authors commented on the irregularity of the fever and the fact that it may have a low or high range. All agreed also that when the patient is in extremis the temperature will fall to below normal. Cabot,[50] writing in Osler's System, commented on the fact that he had witnessed cases in which the degree and duration of fever forced the consideration of typhoid in the differential diagnosis. One cannot obtain any definite statement as to the significance of the temperature, but by reading various papers on the subject, one gathers the impression that temperature is significant in a well developed case and is not to be considered either as an early or as a late phenomenon. It is probably present largely when the patient is on the downward path. In the case reported below, the occurrence of an exceedingly high temperature was very striking. As is characteristic, the patient felt better than she had felt for days, when

her temperature was 103.8. As will be noticed from the chart, this was very shortly after the commencement of liver therapy. It is unfortunate that we did not obtain blood pigment studies, but, if we may quote Russell,[76] "The icterus index in these cases becomes normal prior to the manifested in Addisonian anemia. This occurrence of temperature would correlate with the finding of Alt,[77] who observed in five cases of this disease a positive nitrogen balance of marked degree immediately after the beginning of therapy.

rise in the reticulocytes." Thus, in our case the dropping of the icterus index from a high figure to normal would have been during this period of pyrexia. It seems to us that, while this is an unproved fact, it coincides with certain suggestions as to the nutritional and metabolic disorders

Case Report

Hospital number, 1388; female; 38; married; occupation housewife.

A housewife, aged 38, was first seen in May, 1927. At that time she complained of weakness of a month's duration. The patient appeared very pale at the time

and had a rapid heart with a hemic murmur. Hemoglobin was 50 per cent.

We next saw the patient on March 19, 1929, at which time she complained of the same tired feeling that was present two years previous. In addition she was very nervous, had a humming in the ears, and a pins and needles sensation in the feet and legs, extending as high as the knee.

Family history was unimportant. The latter of her two pregnancies was nine years ago.

Physical examination. The patient is well developed, poorly nourished, and lying quietly in bed in no apparent pain. The skin is very pale, with a slight yellowish tinge. The hair is dry; it is not gray. Eyes react to light and accommodation. No nystagmus. No coloring of the sclera. Nose and throat negative. Mouth: upper and lower plates. Tongue very smooth with two reddened areas along the edge. Neck: slight enlargement of thyroid, over which can be heard a systolic but not a diastolic bruit. Lung excursion is normal; resonance normal, and no râles. The heart is normal in position and size. Apex beat very forceful and no murmur is heard. Pulse 110. B. P. 130/80. Abdomen slightly scaphoid; no point of tenderness. Neither liver nor spleen are felt. No trophic ulcers or other abnormalities of the extremities.

Special examination: ophthalmoscopic examination shows normal disc with normal arteries and veins, the only exception being a moderate compression at some of the arterovenous crossings. There is no beating or any evidence of either old or recent hemorrhage. Neurological: cranial nerves negative. Abdominal reflexes negative. Neither the biceps, triceps, knee jerks, nor ankle jerks could be obtained. Over the entire body up to the level of the sternum there is a complete absence of vibration sense. There is little or no disturbance as to touch and none as to muscle pain. Position sense is markedly decreased in the left foot and to a lesser extent in the right.

Laboratory: urine examination upon many occasions was negative, both chemically and microscopically. Blood counts are shown in the chart. The smear shows anisocytosis, poikilocytosis, and increase in size of the red cells. White cells are essentially normal. Van den Bergh and gastric secretions were not done.

SUMMARY

1. The existence of high-grade idiopathic anemia, progressively fatal, was first described by Coombe[2] of Edinburgh in 1820. It was later redescribed by Channing[3] in 1842, Addison[4] in 1849, and Biermer[10] in 1872.

2. Pathological knowledge of the disease was complete by 1880 except for the neurological findings which were added in 1887, the glossitis in 1889.

3. Arsenic was first used by Bramwell[17] of Edinburgh in 1877.

4. The period of liver therapy was inaugurated by Minot and Murphy[44] in 1926 and has reopened the controversy as to whether the disease is essentially a metabolic disorder or the sequela of a chronic infection.

5. The occurrence of temperature has been noted since Biermer's original description of the disease. Its significance is doubtful, but its occurrence in the case reported coincided with a period in which there is a reduction to normal of the icterus index and a marked nitrogen retention.

NEW TREATMENTS FOR CANCER

Hanson reports results closely resembling those described by Coffey and Humber, following the administration of thymus extract. Sokoloff reports similar results following the use of an extract of the suprarenal combined with iron. Charlton announces lytic effects on cancer cells following the administration of an extract of the omentum. The interest of the Coffey-Humber method, in its present stage of investigation, lies primarily in the fact that the available evidence seems to demonstrate a definite effect on cancer tissue as the result of injecting suprarenal extract into the body at points removed from the tumor. (Jour. A. M. A., March 1, 1930, p. 639.)

CAUSYTH

A number of German journals have contained more or less llaudatory reports regarding Causyth, but these are not considered to present acceptable evidence for the value of the preparation. According to the advertising, Causyth is a "cyclohexatrienpyridinsulphonacid, derived from Pyrazol, the formula being $C_{22}H_{24}N_4O_5S$." The product has not been considered by the Council on Pharmacy and Chemistry nor has the Mallinckrodt Chemical Works, which exploits it by way of its Canadian branch, "Mallinckrodt Chemical Works, Limited, of Canada," requested the Council to report on it. Apparently no reports have been published in American medical journals which are confirmatory of the German propaganda. A pharmacologist who has given much attention to the action of salicylates and other drugs used in the treatment of rheumatism reviewed seven of the eight papers which were referred to in an advertising circular. He held the evidence to be unsatisfactory and uncritical and no justification for the extravagant claims of the advertising. (Jour. A. M. A., March 1, 1930, p. 656.)

PNEUMOCOCCUS VACCINES OMITTED FROM N. N. R.

The Council on Pharmacy and Chemistry reports that increasing experience has failed to demonstrate the value of pneumococcus vaccine in the treatment of pneumonia, and the prophylactic value of the vaccine has not been conclusively proved. The Council came to the conclusion that the experience with this vaccine has not afforded acceptable evidence for its therapeutic usefulness and voted to omit it, with the accepted brands, from New and Non-official Remedies. In accordance with this action the Council announces the omission of Pneumococcus Vaccine Immunizing (Gilliland Laboratories, Inc.); Pneumococcus Vaccine (Lederle Antitoxin Laboratories); Pneumococcus Vaccine, Prophylactic (Eli Lilly & Co.); Pneumococcus Antigen-Lilly; Pneumococcus Vaccine (National Drug Company); Pneumomoccus Vaccine (Four Types) (Parke, Davis & Co.); Pneumococcus Immunogen (Parke, Davis & Co.); Pneumococcus Vaccine (E. R. Squibb & Sons). (Jour. A. M. A., March 8, 1930, p. 716.)

SYRUP OF ALFEMINE, ET AL

Sherman L. Divis, Ph.D., is Professor of Chemistry and Director of Nutritional Research in the Indiana University School of Dentristry. He is neither a physician nor a dentist. During the past few years Professor Davis has been doing a good deal of lecturing before dental societies. In his talks Professor Davis recommends certain proprietary medicinal products, four in number: "Syrup of Alfemine," "Vicodol," "Caperoid Tablets" and "Vicaperol Capsules." All of these products used to be manufactured by the Ucoline Products Co. of Indianapolis. The manufacture and distribution of these products has been taken over by the Rochester Laboratries, Inc., Rochester, Minn. It appears that the Rochester Laboratories distribute the preparations on a royalty basis; the royalties being turned over to the trustees of Indiana University. Professor Davies does not receive any part of the royalty. Undoubtedly, the newly formed Council on Dental Therapeutics created by the American Dental Association will, in due time, investigate and report on the formulas of Professor Davis that are sold under proprietary names. Meanwhile, the entire arrangement constitutes an unusual scheme in its relationship to the practice of either scientific medicine or dentistry. (Jour. A. M. A., April 12, 1930, p. 1163.)

INCIDENCE OF BOVINE TUBERCULOSIS IN HUMANS, AND REPORT OF THE OFFICIAL CONTROL AND ELIMINATION OF BOVINE TUBERCULOSIS IN MINNESOTA*

CHARLES E. COTTON
Secretary and Executive Officer, Minnesota State Live Stock Sanitary Board
Minneapolis

WHEN I received the invitation to present this paper, I replied that I did not think it proper for a veterinarian, engaged in administrative control work, to present a paper or make any statements to the medical profession relative to the types of tuberculosis in the human family. Your program committee was persistent, and I agreed to include a review of the evidence of the authorities and laboratory workers on this subject.

The State Live Stock Sanitary Board, since its origin in 1903, has extended service in the control and elimination of tuberculosis in cattle to cattle owners supplying milk to the cities and villages throughout the State, and also to any herd owners who are willing to coöperate with the Board and who would agree to slaughter their reacting or diseased cattle. The city of Minneapolis was the first city in the United States to adopt the ordinance requiring that raw milk should be derived from cattle that have passed satisfactory tuberculin tests. Minnesota was the first state in the Union to adopt the plan of accrediting herds of cattle as free from tuberculosis, and the plan adopted by Minnesota was later adopted as the cooperative plan by the Federal Bureau of Animal Industry with all the states in the Union.

In 1923 Minnesota, coöperating with the Federal Government, adopted the Area Plan for the control and elimination of the disease from cattle, by counties. This work has progressed very rapidly but we are constantly met with opposition instigated by the American Medical Liberty League, which, as you know, has large sums of money available for distribution of propaganda in order to influence legislation against every movement of modern preventive medicine. They quote statements of so-called physicians, and also extracts of articles of recognized scientists, of unproven or impractical theories. We frequently have statements circulated which are claimed to have originated from reputable physicians, quoting Doctor Robert Koch, and many of these statements claim that Koch never changed his views or modified them, up to the time of his death.

In 1901 Doctor Koch stated before the London Congress on Tuberculosis that the germs obtained from human sources were not the same as those obtained from cattle, and there was practically no danger of man contracting tuberculosis from cattle, or about as much danger to man as there was from the inheritance of the disease, which, of course, means nothing at all. He stated he did not deem it advisable to take measures against the spread of the disease from cattle to human beings. Koch's views were immediately studied by many scientific investigators throughout the world. The German Government authorized an investigation and the British Government appointed a Royal Commission. Pennsylvania, the New York City Health Department and the United States Bureau of Animal Industry also carried on investigations. The evidence disclosed by these investigators completely disproved Koch's opinion relative to the transmission of bovine tuberculosis to man and, as a result, Koch later changed his views; but he never fully accepted the results of the other investigators.

At the Sixth International Congress on Tuberculosis in Washington in 1908, when Doctor Koch was met with almost unanimous contrary opinions from other scientists, he opened the discussion on "The Relation of Bovine and Human Tuberculosis,"[1] by saying: "Human beings may be infected by the bovine tubercle bacillus, but serious diseases from this cause occur very rarely and preventive measures against tuberculosis should therefore be directed primarily against the propagation of human tubercle bacilli." He referred

*Presented before the Hennepin County Medical Society, Minneapolis, March 7, 1930.

to possible errors in the research work of others and stated that "The experiments of the British Commission failed in several respects, and all other work which has come to my notice answers these requirements so poorly that I can grant them no weight, at least as regards the occurrence of bovine tuberculosis in man." Among the speakers who contradicted Koch's opinions and defended their methods of investigation were Professor G. Sims Woodhead of Cambridge, England; Johannes Fibiger of Copenhagen; M. P. Ravanel of Madison, Wisconsin; Professor Charles W. Duval of Tulane University, New Orleans; and Doctor Charles F. Dawson of Newark, Delaware. Doctor Koch afterwards declared he had never denied that bovine tuberculosis is found in man, and tried to limit the discussion to the consideration of bovine tuberculosis in the lungs of human beings. He asked whether any cases of pulmonary tuberculosis existed in which bacilli of the bovine type of tuberculosis were found. When Professor S. Arloing of Lyons, France, Professor G. Sims Woodhead of Cambridge, England, and Professor Fibiger of Copenhagen mentioned such cases Koch again[2] questioned the accuracy of their investigations and reports, and finally concluded by saying, "I admit that bovine infection can occasionally occur, and I desire not to be understood as disregarding the endeavors to extirpate bovine tuberculosis, as far as these endeavors are dictated by agricultural and economic reasons; but I mean it would be wrong to give to these proposals the leading place in front of the efforts to combat human tuberculosis."

Koch's opinion as to the transmissibility of bovine tuberculosis to man was conclusively disproved by the final report of the British Royal Commission, presented after nine years of study and investigation.[3]

This report was practically duplicated by research men in Germany, France, Denmark and the United States, and under ordinary circumstances we would conclude that the question of the menace of bovine tuberculosis to man had been settled twenty years ago. However, a few followers of Koch have continued to support his opinions and, as a result, some laymen make exaggerated statements supporting Koch's ideas. From data, statistics and reports, a conservative estimate of the incidence of bovine tuberculosis in human beings is twenty-five per cent of the cases of tuberculosis in children and five per cent of all types of tuberculosis in man.

The World War interrupted the research work on this subject but since then the majority of the reports have come from investigations in Great Britain. Doctor A. Stanley Griffith summarized the data on this subject before the National Milk Conference in London in 1922.[4] He reported the study of types of bacillus of tuberculosis in 1,215 cases in England and Scotland; of the total number, 935 or seventy-seven per cent, were of human origin, and 280, or twenty-three per cent, were of bovine origin. He showed tables of the different types of tuberculosis in man, which disclosed that of 116 cases of tuberculosis of the cervical glands, 46.5 per cent were of the bovine type; that of 476 cases of tuberculosis of the bones and joints, in England and Wales, 18.3 per cent were of the bovine type; and of 28 cases in Scotland 28.6 per cent were of the bovine type; of 126 cases of lupus, 50.8 per cent were of the bovine type; of 52 cases of scrofulodermia, 38.4 per cent were of the bovine type; of 17 cases of tuberculosis of the genito-urinary tract, 17.6 per cent were of the bovine type; of 12 cases of tuberculosis of the meninges, 16.6 per cent were of the bovine type; of 229 cases of the lungs, 1.31 per cent were of the bovine type. He also reported an autopsy of children, of which 113 were classed as local government board series; twenty of these, or 17.7 per cent, were of the bovine type. Also, an autopsy of 46 children of the Royal Commission series, of which 19, or 41.3 per cent, were of the bovine type. Griffith concluded: "That bovine tuberculosis is an important source of human tuberculosis in Great Britain." The bovine tubercle bacillus shares in the production of all of the chief clinical varieties of human tuberculosis and causes an appreciable loss of life, especially in children. The proportion of bovine to human infections is highest in children under five years of age and in those forms of tuberculosis which are primary in the alimentary tract. The age incidence and the anatomical distribution of the primary lesions clearly point to cow's milk as the source of the infection with bovine bacilli and it ought

not therefore to be used for human consumption. Stringent measures should be taken to prevent the sale of such milk. He further states it is estimated by Cobbett, his associate, that the "bovine type of bacillus causes 6.41 per cent of the total deaths from tuberculosis of all kinds in England and Wales, or approximately 3,000 deaths every year."

The percentage of bovine infection in pulmonary tuberculosis in man (1.3) is much higher in England and Wales than in other countries, from reports which have been made.

Doctor Griffith presented a paper[5] at the Eleventh National Conference on Maternity and Infant Welfare in London on July 5, 1929, dealing with 541 cases of tuberculosis of the bones and joints. Of the patients, of all ages, 18.7 per cent disclosed the bacilli of the bovine type. Children under five years of age (102 cases) disclosed the bovine type in 30 per cent, and children under ten years of age (327 cases) disclosed the bovine type in 25 per cent.

In the official journal of the Pathological Society of Great Britain and Ireland, Griffith[6] reports the results of the work done by his colleagues on the Tuberculosis Commission, and himself, on types of tubercle bacilli and other varieties of human tuberculosis.

Table I gives the percentages of human and bovine tubercle bacilli found in the investigation of human tuberculosis:

*Including one of the two mixed viruses.
†Including one mixed virus.
‡Including two mixed viruses.

Griffith further stated: "The results of the bacteriological examination of post mortem material have shown that when the primary lesions are in the thorax the infection is of human origin in about 99 per cent of the cases. When, on the other hand, the primary lesions are in the mesenteric glands, only 15 per cent are 'human.'"

Some contended that tubercle bacilli are not found in the milk unless there are lesions in the udder and that only cows with such lesions should be excluded from the milk supply. The reports of the British Royal Commission,[7] Rabinowitch and Kempnes,[8] and Mohler,[8] Chief of the Federal Bureau of Animal Industry, in his review of the evidence which had been accumulated on this subject, are conclusive that the bacilli are at times present in the milk of tuberculous cows presenting no evidence whatever of diseases of the udder, even on postmortem examination.

Klein in "Principles and Practice of Milk Hygiene," states, "Anderson examined 233 samples of milk in Washington in 1906 and found tubercle bacilli in 6.72 per cent. In Philadelphia in 1908, Campbell examined 130 samples of raw milk and found tubercle bacilli in 13.8 per cent; 12 samples of milk sold as 'pasteurized' were also examined by him and one sample, or 8.3 per cent, contained virulent tubercle bacilli. Hess found tubercle bacilli in 16 per cent of the samples he examined in New York in 1909, and of 144 samples examined by Tonney of Chicago in 1910, 10.5 per cent were infected with tubercle bacilli."

When Doctor Bundeson, the Commissioner of Health of the City of Chicago, was making his fight for "Milk from healthy cattle," he obtained the services of Doctor Archibald of our Minnesota State Board of Health, to make a survey of the commercially pasteurized milk. Archibald found tubercle bacilli in 16 per cent of the samples.

Doctor L. Van Es of the University of Nebraska has been making extensive investigations for a number of years of the types of the tubercle bacilli in tuberculous material from man and the different species of animals, obtained from all parts of the United States. For the past six years he has made special investigations of the incidence of avian tuberculosis from specimens obtained from swine and cattle slaughtered at public abattoirs throughout the United States where the Federal Government maintains inspection. He has furnished me with the tentative results obtained by him prior to December 1, 1929, of the host relations of the three types of tubercle bacilli, namely, bovine, human and avian. He is not ready to publish the results of his work, but, without doubt, they will be published some time this year.

He reports the examination of 393 specimens of human lesions other than pulmonary lesions, of which 11 were of the bovine type, 217 the human type and 165 were negative. He was unable to find bacilli of the avian type in any of the 393 cases. He also reports examining and typing specimens of three cases of Hodgkin's disease of the human family, all of which were negative. He examined 164 isolated lesions obtained from the cow, most of which were lymph nodes, of which 100 disclosed the mammalian type of bacilli, 11 were of the avian type, 4 were mixed and 49 were negative; 40 cases of skin tuberculosis in the cow were all negative as he could not find any living bacilli; 5 lesions of the bovine uterus all typed negative; 58 cases of generalized tuberculosis were of the bovine type. He examined 258 isolated lesions obtained from the hog, the majority of which were lymph nodes, of which 12 were of the mammalian type, 199 avian, 14 mixed and 33 negative. One case of pulmonary tuberculosis in the sheep which was of the bovine type. Two cases of tuberculosis in the horse which were of the bovine type. Six cases in the monkey, of which 3 were of the bovine type, one of the human type and 2 were negative. Lesions obtained from two cases of tuberculosis in the fox, of which one was bovine and one negative. In chickens and pigeons 110 cases, of which 104 were the avian type, one mixed and 5 negative.

You will note that of the 393 specimens obtained from man, of lesions other than pulmonary, he was unable to disclose a single case of the avian type. He has summarized his work, tentatively, and concludes that in tuberculosis in man, other than pulmonary, the bovine type is of moderate or conditional virulence, the avian of very slight, if any, virulence, but his data are insufficient for a definite conclusion, as the typing of some of the specimens gave atypical results. In the cow the human type of tuberculosis is avirulent and the avian type is of very slight virulence and is local and non-progressive. In swine the bovine type is of full virulence, extensive and progressive; the human type of slight virulence, local and non-progressive; the avian type of moderate or conditional virulence, local and with a tendency to generalization. Tuberculosis in dogs, both the bovine and human types, are of moderate or conditional virulence and he has found no cases of the avian type in this animal.

Doctor Charles H. Mayo of Rochester,[10] in a paper presented before the American Veterinary Medical Association in August of 1928, stated that "In Minnesota from 1910 to 1925, inclusive, 34,570 persons died of tuberculosis, all but 6,343 of tuberculosis of the lungs. On five per cent of the total basis, this would mean that 108 persons died every year of bovine tuberculosis. It has been estimated that .5 per cent of the cases of tuberculosis of the lungs and 10 per cent of other forms of tuberculosis are caused by the bacillus from cattle. On this basis, 48 persons died every year of bovine tuberculosis. If we accept this lowest estimate of 48 annual deaths, in addition to the hundreds of cases of bovine infection which result in crippling and incapacitating the victims for a long period or the rest of their lives, I am sure we are justified in all our efforts to eradicate bovine tuberculosis."

One could continue to quote statistics from recognized authorities indefinitely. There is not a single recognized authority who doubts the transmission of bovine tuberculosis to man, but there still remain a few physicians who minimize the danger, even to the extent of opposing the efforts to eradicate the disease from cattle, claiming it is so slight that it is not a public health problem.

At the present time 163 cities and villages in Minnesota have milk ordinances requiring

that all cattle from which raw milk is derived for human consumption must pass satisfactory tuberculin tests approved by the State Live Stock Sanitary Board. The United States Public Health Service recommends that all cities adopt a model ordinance they have prepared, which requires that all milk shall be derived from cattle that have passed satisfactory tuberculin tests, and also be pasteurized for the purpose of eliminating the possible bovine infection and other milk-borne infections. There is no question but that all medical men engaged in the control of, or who are responsible for, communicable diseases in the human family, are agreed that milk from cattle untested for tuberculosis and not supervised as to sanitary practice, should be pasteurized.

In the European countries, except Denmark and in the British Islands, no official control measures of bovine tuberculosis have been made and, as a result, the disease has increased. The percentage of tuberculosis in cattle in the British Isles, according to authorities, is 40 per cent, and it is higher in France.

The Sanitary Authorities in Great Britain are now divided in their opinions relative to the control and elimination of the disease. Some insist that they should adopt the plan of this country and tuberculin test all cattle and slaughter the infected ones; there is another faction that condemns this procedure, claiming it would result in a milk famine and would not be economical.

Doctor Charles McNeil,[11] lecturer in diseases of children, Royal Edinburgh Hospital for Sick Children, states in the British Medical Journal of October 12, 1929: "The widespread existence of tuberculous milk constitutes the greatest and most serious example of food poisoning in this country, and gives Great Britain a 'bad eminence' in this matter over almost every other great state in the Old and New Worlds. There is no general agreed policy, either national, municipal, or private, to meet this danger. Until all of our dairy cattle are free of tubercle there are two ways of dealing with the situation, either that the public health authorities require and supervise the pasteurization of all milk supplies for young children, with the exception of certified milk, or that the medical profession unanimously recommend the boiling in the home of all milk for children."

The most ardent supporters of pasteurization are forced to admit its limitation; in practice it can be applied to only the larger cities. This leaves a large majority of the entire population without a practical means of its application. The only solution offered by the advocates of pasteurization, where it can not be practiced, is to boil the milk.

In the light of experiments in animal nutrition, and the recent experiments in the growth of children, raw milk stands supreme, pasteurized milk second and boiled milk a poor third. It is apparent from these experiments that pasteurization destroys the nutritive balance, and as the higher temperatures are applied the unbalancing is more pronounced.

Thirty-five years ago Doctor Bang of Denmark initiated a plan of control of the disease, providing for the tuberculin testing of all cattle, isolating reactors from the non-reactors on the same farm and the pasteurization of the milk and all milk products. The calves from infected mothers are immediately removed to nurse healthy mothers, or are fed on pasteurized milk. This plan has since been known as the Bang System. Owing to the high percentage of infection in Denmark at the time this system was inaugurated, the claim was made that it was the most practical and economical system to control the disease in cattle. The results as disclosed are certainly conclusive that their system is impractical for the reason that there is as high a percentage of tuberculosis in that country at the present time as there was thirty-five years ago. The reason for this, as I understand it, is the fact that it is an intensive dairy country and the farmers, to a large extent, depend upon the dairy cow for at least a part of their incomes, and they are not so financially situated that they can carry out—nor do they properly carry out—the Bang principles.

In this country thirty-five years ago we started out on the fundamental fact that we must stop the perpetuation of the bovine organism through cattle by slaughtering the reactors. This was accomplished by the tuberculin test and the condemnation of any animals revealing clinical tuberculosis. We have found that tuberculin from the time it was first

used up to the present day has been consistent in its action. This has led to the discovery of many interesting facts in connection with the behavior of the organism.

In 1918 it was the general belief that the only source of infection in the hog was the bovine organism. It was believed, if counties were tested and cattle tuberculosis eliminated, that hog tuberculosis would automatically cease. However, the result was that the condemnation of carcasses of hogs slaughtered under inspection was reduced to practically nil, while the retentions of the carcasses for tuberculosis were only slightly reduced. This was called to the attention of the research workers and it was soon discovered that the hog was not only the host of the bovine type of tubercle bacilli, but of the avian as well. In fact, retentions in hogs at government packing houses are upwards of 80 per cent avian tuberculosis. There is no extensive invasion of the avian type in hogs and no condemnation of carcasses results. Hogs infected with the bovine bacilli react only to the mammalian tuberculin and those infected with the avian type react only to the avian tuberculin. Cattle are resistent to the avian type, as laboratory experiments show that it requires a heavy inoculation of avian tuberculosis material to cause a reaction to avian tuberculin, and the period of sensitization disappears within sixty days.

Tuberculin is consistent in detecting tuberculosis. It reveals the disease before macroscopic lesions develop.

In 1918 the Federal Government, through the Bureau of Animal Industry, initiated a plan for the eradication of tuberculosis by cooperating with the Live Stock Sanitary authorities of the various states. Minnesota was the first state in the Union to sign the agreement with the Federal Government. From 1918 to 1923 this coöperative work was limited to the control and elimination of tuberculosis under the Individual Accredited Tuberculosis-Free Herd Plan, and in 1923 the Legislature passed a law providing for the control and elimination of the disease, by counties, under the Area Plan. This law provides that when fifty-one per cent of the cattle owners sign the petition the Board of County Commissioners, at their discretion, may enter into an agreement with the Sanitary Board, and further provides that the county shall make an appropriation to assist in the cost of the payment of the necessary tuberculin tests until the county is accredited. The State and Federal Government pay indemnity to the cattle owners for cattle that are condemned and slaughtered. Uniform Rules and Regulations for the elimination of tuberculosis under the Area Plan have been adopted by the Federal Bureau of Animal Industry and the Live Stock Sanitary authorities of every state in the Union. These Rules provide that if the complete test of all the cattle in the county discloses a percentage of one per cent or more, a second complete test of all the cattle shall be made a year thereafter; or if any complete test of all the cattle discloses a percentage of one per cent or more, then another complete test shall be made one year thereafter. If the test discloses a percentage of less than one per cent, the infected herds shall be retested until the percentage of infection in the entire county is reduced to .5 of 1 per cent or less, when the county will be officially designated as an accredited tuberculosis-free area for a period of three years. When any test discloses a percentage of less than one per cent, a quarantine of the infected herds is established in order to prevent the owners selling cattle to be added to herds that have passed complete negative tests. We continue to retest all herds in which infection is disclosed, each 120 days until every herd in the county has passed a complete negative test.

Our State law provides that the county's appropriation shall be used to assist in the cost of the payment of the expense of the testing until the county is accredited. After a county is accredited the state shall make all the necessary tests to eliminate the infection from the remaining infected herds, and also make the necessary retests after the three year period of accreditation has elapsed, all without expense to the county.

Of the eighty-seven counties in the State, fifty-four have taken advantage of the State law and have applied to the Sanitary Board for the control of tuberculosis under the Area Plan. Forty-three of these counties are officially accredited. We have six more counties in which at least one complete test of all the cattle has been made; five counties are on the waiting list. We have eleven counties in which the majority of the cat-

tle owners have signed petitions to the County Boards, but the County Boards have refused to recognize such petitions, apply for the test and enter into the agreement with the Sanitary Board. Some of the counties failed to take advantage of the law because of financial reasons, and we are informed that the majority of them were influenced by propaganda that is being circulated by the American Medical Liberty League. Petty politics within the Boards of County Commissioners has also been a deciding factor.

The highest percentage of infection disclosed in any county on the first complete test of all the cattle was 5.4 per cent and the lowest percentage was in Cook County, in which the cattle population was only 565; no reactors nor tuberculous cattle were disclosed.

The counties of Carlton, St. Louis, Lake and Itasca disclosed a percentage of less than .5 per cent on the first complete test. The counties of Red Lake, Marshall, Kittson, Norman, Isanti and Kanabec disclosed a percentage of less than 1 per cent and more than .5 per cent. All of the other accredited counties disclosed a percentage of one per cent or more and we were compelled to make a second complete test and also two retests of the infected herds. By so doing we were able to reduce the percentage so that the second complete test resulted in disclosing a percentage less than 1 per cent.

Time will not permit me to furnish the data of the tests of the individual counties. All of the counties in the immediate vicinity of the Twin Cities are now officially accredited; however, we have a few infected herds in each county which are under quarantine, which we will continue to retest until all of them have passed a negative test.

Hennepin County shows a fair average of the status of the counties in southern Minnesota and for this reason I am furnishing the data of all the tests in this county.

The first complete test was made in September of 1928, which test disclosed 3,753 herds containing 37,933 cattle, of which 1,434, or a percentage of 3.7 per cent, reacted to the test and were officially condemned and slaughtered. In this test we did not include accredited herds that were not due for the test.

There were 507 herds, or a percentage of 13.5 per cent, in which reacting cattle or those giving suspicious reactions were disclosed.

In December of 1928 we retested 517 infected herds containing 8,366 cattle, of which 162 or a percentage of 1.93 reacted. There were 113 herds in which reactors or animals giving suspicious reactions were disclosed.

In April of 1929 we retested 131 infected herds containing 3,016 cattle, of which 48 reacted, or 1.55 per cent. There were 21 herds in which reactors were disclosed.

In September of 1929 we made the second complete test of all the cattle in the county and tested 3,711 herds containing 40,752 cattle, of which 146 reacted, or a percentage of 0.35 per cent, and the county was officially accredited for a period of three years. There were 121 herds in which reactors were disclosed.

In December of 1929 the infected herds were retested and the cattle in all but 22 herds passed a satisfactory test. The remaining 22 herds will be retested in April and all infected herds will be subjected to a retest each 120 days until they have passed satisfactory tests.

We have nine counties in the State whose three year period of accreditation has elapsed and in which we have made a complete test of all the cattle. In four of these counties the percentage of infection disclosed on the test after the three year period of accreditation elapsed was less than .5 per cent and in five of them it was under the 1 per cent. We therefore officially reaccredited the four counties after the complete test was made and the other five counties after making a retest of the few infected herds.

Table II shows the percentage of infection in the nine reaccredited counties on the initial test for the first accreditation and the percentage disclosed three years after they were accredited:

TABLE II

	Percentage Initial Test for Accreditation	Percentage Reaccreditation Test
Freeborn	5.40	0.29
McLeod	4.94	0.24
Scott	2.61	0.32
Traverse	3.44	0.46
Wilkin	3.59	0.55
Faribault	3.11	0.98
Meeker	3.58	0.78
Murray	4.31	0.68
Red Lake	0.988	0.65

The percentage of infection after the three years did not have any connection with the ex-

tent of the disease disclosed on the first test of all the cattle in the county, but on the location of the county and the observance of the quarantine provision relative to importation of cattle. The last five counties were surrounded by non-tested counties.

The result of the retest of the cattle in these nine accredited counties is certainly conclusive and shows that the work is practical, permanent, and the public expense justified. To my mind, it is also a complete answer to all the propaganda and the false statements that are being circulated throughout the State and the country condemning the work. Without doubt, since we have succeeded in building up larger accredited areas, the danger of the infection being reintroduced into these accredited areas will be practically nil and will certainly reduce the incidence of tuberculosis in the human family in these areas.

Every state adjacent to Minnesota, and in fact throughout the United States, is coöperating with the Federal Government in eradicating bovine tuberculosis under the Area Plan of Control.

The counties in Minnesota that are accredited and those in the process of accreditation represent the territory in which sixty-one per cent of the cattle population of the State exists and also the territory in which the highest percentage of tuberculosis was known to exist. We are well over the top and the future expense for the eradication of tuberculosis from all the cattle in Minnesota will continue to be less each year. Any funds expended in the control of the disease after the State is accredited will simply be good sound insurance.

The States of North Carolina and Maine are officially accredited. Indiana and Michigan expect to be accredited within the next few months. The cattle in all but one of the counties in Wisconsin have been tested at least once under the Area Plan. The States of Iowa, Illinois and Indiana have recently passed legislation making the test of all the cattle throughout the State compulsory under the Area Plan of eradication.

During the fiscal year terminating June 30, 1928, we tested over 1,400,000 cattle in the State of Minnesota. During the fiscal year terminating June 30, 1929, we tested 1,325,629 cattle. Of this number 1,139,845 were tested in our official coöperative work with the Federal Government. The remainder were tested by practicing veterinarians under the supervision of the State Live Stock Sanitary Board. These figures do not represent the number of individual cattle tested as we retest all cattle in herds in which reactors are disclosed, each 120 days. Therefore, this total number includes cattle that have been subjected to one or more tests during the year.

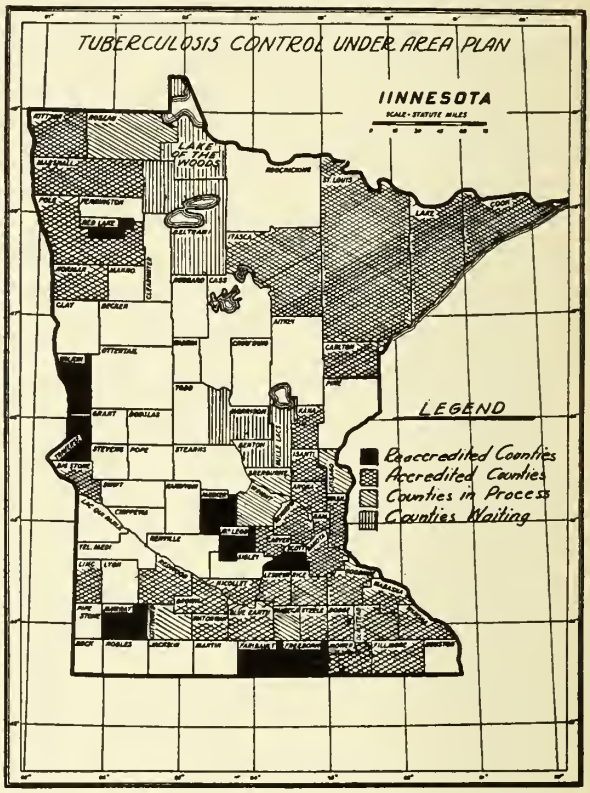

Table III shows the counties that are accredited, the counties that have been reaccredited after the first three year period of accreditation has elapsed, the counties that are in the process of accreditation and in which at least one complete test has been made, and the counties in which the Boards of County Commissioners have furnished agreements to the Live Stock Sanitary Board and which are on our waiting list to be tested.

ACTION OF PHENOLPHTHALEIN

One should always think of the possibility of a phenolphthalein eruption when studying the etiology of a puzzling exanthem. As phenolphthalein is chiefly excreted into the intestine by means of the bile, and reabsorbed from the colon, there is a tendency for its action to continue for several days. Hence, its continued daily use may lead to ultimate overaction with diarrhea, abdominal pains, tenesmus and bleeding. (Jour. A. M. A., April 12, 1930, p. 1165.)

VAN ARD SANATORIUM

The Van Ard Sanatorium, Inc., does a quack rheumatism-cure business from an old brick residence on the South Side of Chicago. It is an Illinois corporation with an authorized capital of $10,000. Its officers are listed as J. B. Creevy, President; H. L. Cassel, Secretary. They are the same individuals who are, or were, connected with the "Cass Treatment for Rheumatism." The impression is given in the Van Ard advertising that Charles J. Cahill, who is connected with the business of the firm, has special knowledge of the treatment of rheumatism. Needless to say, Cahill's name is unknown to scientific medicine. Just as in the Cass Laboratories fake the letters were signed "Harvey L. Cass" (a person who didn't exist), so in the Van Ard Sanatorium quackery most of the letters are signed "J. B. Crenon, Secretary." And just as "Harvey L. Cass" was really Harvey L. Cassel, so, doubtless, "J. B. Crenon" is Joseph B. Creevy! Reports were received from California of three deaths in which the principal autopsy finding was an extreme degree of atrophy of the liver. The reports brought out that two of the women had been taking the Van Ard "treatment," while the third had been taking the Cass "treatment." From the results of chemical analyses carried out in the A. M. A. Chemical Laboratory it may be stated that the Van Ard treatment consists essentially of acetylsalicylic acid (aspirin), cinchophen, sodium bicarbonate (baking soda) and a laxative. It is obvious that the Van Ard and Cass "treatments" are for all practical purposes identical. In the Cass treatment it was epsom salt, flavored, while in the Van Ard treatment it seems to be phenolphthalein and aloes. (Jour. A. M. A., April 19, 1930, p. 1255.)

"S. C. A." SOLUBLE ANTIGEN, "S. C. A." SERUM EQUINE (CONCENTRATED), AND "S. C. A." SERUM BOVINE (UNCONCENTRATED).

The Council on Pharmacy and Chemistry issues a preliminary report reviewing the available evidence published by J. C. Small concerning preparations stated to represent products obtained from the bacterium claimed to be the cause of rheumatic fever. Preparations of this organism were presented to the Council by the H. K. Mulford Co. as S. C. A. Soluble Antigen, S. C. A. Serum Equine (Concentrated) and S. C. A. Serum Bovine (Unconcenrated). The Council decided that the published work of Small does not offer sufficient evidence to warrant the acceptance of the Mulford products. Further doubt has been cast on the value of this therapy by the paper of Dr. May G. Wilson, in which it is reported that the administration of *Streptococcus cardioarthritidis* antiserum and of the soluble antigen of *Streptococcus cardioarthritidis* did not seem to influence the usual clinical course of the disease or prevent the occurrence of relapses. The Council holds that, while the products are suitable for controlled clinical investigation by experimental workers, propaganda which invites their general use is not warranted at this time. (Jour. A. M. A., April 26, 1930, p. 1303.)

ANTIUSTIO NOT ACCEPTABLE FOR N. N. R.

The Council on Pharmacy and Chemistry reports that Antiustio is claimed by the manufacturer, Frederick Laboratory, Toledo, Ohio, to be "The Greatest Burn Remedy in Existence." A circular contains the following indefinite and non-quantitative statement of composition: "FORMULA Solvent Solution of Plumbic MATERIALS Subnitrate of Bismuth Zinc Sulphate and Iodide of Lead combined with mineral waxes." From this and other statements it would appear that Antiustio is a petrolatum-paraffin mixture claimed to contain 5 per cent of bismuth subnitrate along with small but undeclared amounts of zinc sulphate and lead iodide. The Council found Antiustio unacceptable for New and Non-official Remedies because it is an unscientific preparation marketed with an inadequate statement of composition, under a name which is not descriptive of its composition and with claims that are exaggerated and unwarranted. (Jour. A. M. A., November 16, 1929, p. 1559.)

THE PRE-OPERATIVE CARE OF PATIENTS FOR PROSTATECTOMY*

W. N. Graves, A.B., M.D.
Duluth

IN any field of surgery it is our obvious duty to hold the mortality to the lowest possible point. The great discrepancy of the mortality rates in different institutions evidences the fact that in dealing with the enlarged, obstructing prostate some factor besides the surgical technic, *per se,* must be considered as the cause. It has been shown in many clinics that an exact understanding of the abnormal physiology present in these patients and the application of steps to return their functions to as nearly normal as possible, before any operative intervention takes place, will usually lower the mortality to as low as 2 to 5 per cent. In other institutions the mortality is still 25 to 30 per cent because the significance of careful preparation is not understood or, if understood, is not practiced.

In prostatic surgery we are usually dealing with poor primary risks, old men with lowered vitality, 80 per cent with cardiovascular pathology, 50 per cent with pulmonary disease and few with a normal renal function.

Benign hypertrophy of the prostate with obstruction is not unlike any other obstruction, whether it be biliary, gastric or intestinal, with its resultant toxemia. This may be an increased retention of nitrogenous products due either to the breakdown of body protein or a failure of excretion, or other alterations of normal balance in blood constituents, fluid balance, chlorides, carbon dioxide combining power or acid base equilibrium.

After taking a careful history, a complete and thorough physical examination should be made in search of coincidental diseases and, if found, these should be treated appropriately. The urological examination is important and should include an especially careful search for evidence of infection of the kidneys, bladder, prostate, seminal vesicles and epididymes. The immediate laboratory examinations to be made should include blood Wassermann, coagulation time and typing, as well as the usual routine examination. A careful search of the urine should be made for evidences of infection, and if present these should be localized. Blood chemistry should be estimated every three or four days throughout the preliminary management, as it gives direct evidence of the progress the patient is making and aids in determining when the maximum kidney function is reached. Urea nitrogen and creatinin content are the most important, but blood sugar determination should also be made, as by so doing one will occasionally avoid the embarrassment of operating upon a patient in the hyperglycemic state.

If the bladder is palpated or shown by percussion to be above the symphysis pubis, care should be taken not to empty it too rapidly, as these cases with high grade retention frequently develop a suppression of urine if the back pressure is too suddenly released. Decompression may be done by intermittent catheterization, replacing about two-thirds of the amount of urine removed with boric acid or some other antiseptic solution. I feel that frequent catheterization more commonly leads to infections than does a correctly managed inlying catheter. Shaw and Young have devised a very ingenious decompression apparatus, which can be used by the patient in bed or in a wheel chair, and this aids greatly in keeping these patients exercising and thus does not alter the normal habits to any great degree. A decompression can, however, be done very satisfactorily without this apparatus and I feel it should be done in every case that shows a residual above 150 c.c. The following is a satisfactory method: After having the patient void, an inlying catheter is inserted, taking care not to allow the residual urine to escape. The catheter is then attached to a tube leading to a receptacle on a standard at the side of the bed. The end of the tube is raised to the point at which the bladder pressure raises the urine and the level marked, allowing all the

*Read before the St. Louis County Medical Society, Duluth, Minn.

urine which is excreted to flow at this level for the first twenty-four hours. The container is then lowered 5 cm. daily until it reaches a level about 15 cm. above the bladder, after which it may be allowed to drain freely. In cases of more or less acute retention in which the blood chemistry does not show much evidence of kidney damage the drainage level may after a few days be lowered much more rapidly than that stated, though this should not be done in the presence of hypertension or much increase in urea nitrogen or creatinin.

After decompression is completed, a phenolsulphonephthalein functional test should be made and repeated twice weekly in order to watch the progress of recovery of the kidneys. Intravenous administration of the dye is preferable to the intramuscular route because of the fewer sources of error. Employing the intravenous route we are assured that the dye comes into direct contact with the convoluted tubules immediately and there is practically no error in determination of appearance time, which is one of the important parts of this function test.

To avoid complicating infections the daily instillation of various antiseptics into the bladder has given excellent results. Among those commonly used are mercurochrome, silver nitrate, argyrol, oxycyanide of mercury and meroxyl. Of these, meroxyl probably has the most advantages. In strength of 1 to 400 or 500 it is only slightly irritating, actively germicidal and does not have the disadvantage of masking gross blood, or being precipitated by urine, serum, pus, or blood. One ounce of 1 to 400 solution instilled and retained in the bladder for a short time twice daily will not only prevent infection but will aid greatly in clearing up any cystitis which may be present.

Preliminary vasectomy or vasoligation has increased in practice recently and is now being done routinely in numerous clinics. Reports from various clinics show an occurrence of epididymitis in prostatectomy patients varying in frequency from 20 to 80 per cent with a probable average of about 35 per cent. Besides being a painful complication for the patient and a disagreeable one for the surgeon it is also quite an economic complication to the patient. Vasectomy should be done as soon as preparation for the operation is started, preferably before any instrumentation. It is such a minor procedure that it may be done in bed while decompression is going on and without disturbing the patient to any great extent. Rolnick in his experimental work showed that unless at least 1 cm. of the vas is resected there will again be union and unless the sheath surrounding the vas is excised there is considerable danger of epididymitis due to the infection traveling along the lymphatics. Vasoligation does not completely fulfill the above requirements and therefore is not so desirable as a correctly performed vasectomy.

Preliminary cystostomy is necessary in about 25 per cent of the cases. The factors demanding this procedure are: intolerance to the inlying catheter, intercurrent urological infections, psychoses and inability to catheterize the patient. It may also be the method of choice in cases which require prolonged drainage.

The judicious use of fluids, combined with preliminary drainage is without doubt the most important factor in carrying a large percentage of patients through a successful operation. Fluids in sufficiently generous amounts are detoxicating and diuretic, thereby neutralizing and eliminating toxic products, as well as maintaining the normal viscosity of the blood. As soon as drainage is instituted fluids should be forced up to at least 4,000 c.c. daily, and when a uremic or preuremic state exists at may be necessary to give as high as 10,000 to 12,000 c.c. in twenty-four hours. Water may be given in large quantities by mouth but there should be no hesitancy in utilizing the other available routes, *i. e.*, by vein, rectum or hypodermoclysis. The use of 1 per cent sodium chloride solution intravenously, as recommended by Bumpus, is efficient in overcoming the impaired renal function in these patients. It not only increases the blood and tissue fluids but also restores the plasma chlorides to normal. Glucose solutions are advantageous for heat and energy as well as being efficacious in stabilizing the disturbed acid-base equilibrium. It may be given by mouth or rectum but is probably most beneficial when given intravenously in 5 to 10 per cent solutions, whether alone or in combination with 1 per cent saline solution. The chief contraindication to forced fluids is a weakened myocardium and cases so

afflicted should be carefully watched for the first evidence of edema in order that a happy medium may be reached—one beneficial to the kidney without damage to a weakened heart.

By the judicious use of digitalis in valvular and myocardial disease as well as in those with arrythmias, one may, without embarrassment, through its action of increasing the cardiac reserve, eventually get the fluid intake up to 4,000 to 5,000 c.c. daily. Patients with hypertension are also benefited by the use of digitalis and usually go through the operation with less shock than when not digitalized.

It is unwise to operate upon this type of patient too early or before all of the above mentioned preparatory steps are completed. At least ten days of observation, testing and preparation should be made even on men who are apparently in excellent condition. In markedly advanced stages it may require several months of drainage before the functional tests have reached a normal stability and the patient's system is ready to cope with the shock, infections and hemorrhage which may accompany or follow a prostatectomy.

General anesthesia is rarely used today in prostatic surgery. It has been supplanted by the use of novocaine to such an extent that but a small percentage of the prostatectomies are being done with the more dangerous anesthetic. Sacral or epidural anesthesia is satisfactory in 80 to 90 per cent of these cases when combined with adequate infiltration or infiltration block of the abdominal wall. If anesthesia is not complete it can be supplemented most satisfactorily by direct infiltration of the capsule under direct vision.

Spinal anesthesia has much to recommend it in selected cases. Ephedrin has done much to overcome its depressant effect sometimes characterized by an alarming drop in blood pressure. This condition is especially dangerous because it may result in a delayed suppression and consequent uremia.

Neither spinal nor sacral anesthesia has the deleterious effect of general anesthesia upon the pulmonary and cardiovascular systems, which it has been our endeavor to protect throughout the preparation.

In conclusion it may be said that, by careful examination, intelligent understanding of the physiological principles involved, the use of the facilities at our disposal with which to regain a normal physiologic equilibrium, delay rather than haste in operating, and finally, the choice of a safe anesthetic, prostatic surgery will enjoy the position of relative safety it deserves.

410 Fidelity Bldg.

UNDULANT FEVER BACTERIAL VACCINE

The Council on Pharmacy and Chemistry reports that the Jensen-Salsbery Laboratories, Inc., have presented Undulant Fever Bacterial Vaccine (Jensen-Salsbery) for consideration by the Council. This product is stated to be a physiologic saline suspension of *Brucella melitensis* (var. *abortus* 75 per cent, and *suis* 25 per cent). From an examination of the published reports the Council's referee came to the conclusion that this material does not offer adequate evidence for the usefulness of the product and that this form of treatment should be subjected to further controlled clinical trial. The Council voted to publish its preliminary report and to postpone definite action on the question of accepting Undulant Fever Bacterial Vaccine (Jensen-Salsberg) while awaiting the development of further evidence of its therapeutic value. (Jour. A. M. A., April 26, 1930, p. 1304.)

SUN CHOLERA MIXTURE

During the cholera excitement in New York in June, 1849, a physician by the name of G. W. Busteed sent a recipe for the disease to the editor of the New York *Sun*. It was printed, and was so successful in the relief, at least, of the symptoms that it came to be popularly known as the Sun Cholera Mixture. It was admitted to the first edition of the National Formulary in 1883 and in subsequent editions under that name. The original formula called for: tincture of opium, tincture of rhubarb, tincture of capsicum, spirit of camphor, essence of peppermint, equal parts. The formula was modified somewhat later on account of the changing strength of some of the ingredients in later editions of the Pharmacopeia. (Jour. A. M. A., April 5, 1930, p. 1088.)

TRACHOMA PROBLEMS AS DEALT WITH AT THE THIRTEENTH INTERNATIONAL CONGRESS OF OPHTHALMOLOGY*

HOWARD MCI. MORTON, M.S., M.D., F.A.C.S.
Minneapolis

IN view of the notable presence of trachoma among our Minnesota Indians, the subject of trachoma presents uncommon interest to the medical profession and the general public of the state of Minnesota.

The hygienic and social significance of trachoma was accentuated by the attention given it at the last International Congress of Ophthalmology, held at Amsterdam and the Hague, during its session in September, 1929.

The discussion took the form of a symposium, and was participated in by many of the leading ophthalmologists throughout the world, including Wibaut of Amsterdam, Vefik Bey of Turkey, Nouri Hefmi also of Turkey, Riza Sadi of Syria, Hindawy of Arabia, Chams of Persia, Ticho of Palestine, Miyashita of Japan, Soira of Spain, Da Gama Pinto of Portugal, Petit and Magito of France, Selenkowsky of Russia, Grosz of Hungary, Hanke of Austria, Bakker of Holland, Wright of England, Ferguson of New Zealand, Fallen of Luxembourg, Gronhelm of Sweden, Maggiori of Italy, and Brukner of Czecho-Slovakia, and others. The writer listened to many of these addresses and their discussion, and from these, and the printed material obtained at Amsterdam, he will, to the best of his ability, indicate their general trend and significance. This, however, is not easy, for the subject was dealt with to such an extent, and the different phases presented were so numerous, that to present in synoptic form for a short paper is no easy task.

The subject was presented largely from the following viewpoints: (1) the geographic distribution of trachoma and its frequency in these areas; (2) the different methods carried out to obtain statistics regarding trachoma in the different countries; (3) methods to segregate and to prevent extension. Other phases were brought up and discussed, but those just enumerated constituted the framework for the symposium. Very little regarding treatment was said, and this little, simply restated, present well known and usual practices in the treatment of the disease. These largely concerned questions of prevention of infection, usual local medication, and expression. I did not hear removal of the tarsus recognized as a desirable procedure, and, in fact, several times noticed that this method of treatment was disapproved.

So expansive was the material presented that it will be necessary for me to briefly consider these somewhat in orderly arrangement, and to do this, we will proceed in the following manner:

(A) Methods of obtaining statistics. These were as follows:

1. Official statistics based on compulsory notification.
2. Examination of school children.
3. Examination of recruits.
4. Examination of samples of population more or less representative.
5. The number of trachoma patients in proportion to other eye diseases in ophthalmic clinics.
6. The absolute number of trachoma patients known to oculists or general practitioners.
7. Approximations given by oculists or general practitioners who know the country.
8. Trachoma percentage in the causes of blindness.

We may briefly remark upon these, through the assistance of the World Trachoma Map, as presented by Wibaut of Amsterdam. Regarding the first (compulsory notification), the figures obtained are always much too small. In Syria, the official index is but 3 to 5 in 10,000, whereas, in fact, 59 per cent of all the eye cases occurring in Syria are trachoma. In certain parts of Russia, an index of 534 to 10,000 is given, whereas, the real and correct index is 45 per cent of all eye cases. It is to be noted, however, that through compulsory notification we may discover some

*Read by request before the Minnesota Academy of Ophthalmology and Oto-Laryngology, in January, 1930.
This review of an important symposium and discussion on trachoma was made from notes taken at the time of and literature given out during a visit to Amsterdam in September 1929, when, by invitation, an address was also delivered before the Congress.

relative value for different parts of the same country, or different countries.

As regards the examination of school children, we obtain a very exact series of figures, especially when the school population is not a select one, and the diagnosis is made by an experienced oculist. In some countries, however, this percentage may be much too high where there is a frequent occurrence of follicular conjunctivitis, which may not be, or cannot be, distinguished from trachoma.

As regards recruits, statistics are of distinct value when obtained from a country where conscription exists.

As regards four, the examination of samples of population more or less representative, the figures are generally too high, for there is an inclination on the part of the oculist to seek for cases of trachoma if the disease is not very prevalent. Furthermore, the population may either come when they have eye diseases, or may try to evade examination.

As regards five (the number of trachoma patients in proportion to other eye disease in ophthalmic clinics), this is the oldest method of approximation and the one most used by former writers.

The figures obtained by taking the absolute number of trachoma patients known to oculists will be found much too small, since a large number of such patients are never treated, and when the diagnosis is made by general practitioners, many cases are overlooked.

Attention was called to the fact of the diagnostic difficulties presented. A large number of cases resembling trachoma are not necessarily trachoma, and there is much confusion with follicular forms of disease. It is not easy to estimate the influence of race, but as a rule it was thought that the race differences go hand in hand with the differences of social welfare and education. No race seems to be immune, not even the negro, although this has been disputed. There is undoubtedly a predominance of trachoma in the female. Some reports stress the importance played by the general constitutional condition; and general welfare is a factor that is obvious and generally admitted.

As to the causes of the spreading of trachoma, we may state that the contagiousness of the disease is now generally admitted. This has been proven too often to deny. On the other hand, the degree of this contagiousness differs enormously. Cicatricial and chronic granular cases may be only slightly contagious, while the acute cases may be extremely so. As regards the onset, it has been found, in some deliberate self-infections and in some other known cases, to be about from four to ten days, but as regards the incubation period of the more chronic beginning cases, nothing definite is known. As regards the mode of infection, little is known. By direct observation in many countries, it has been proved that it often takes place in the family.

Miyoshita (Japan) shows quite conclusively that not only are infants often infected but that the trachoma percentage in the schools is at its maximum at seven years of age, proving that most school children must have become infected at an early age at home. The rôle of the mother as the source of infection is not so prevalent as has been contended. Sobhey Bey informs us that in Egypt nearly all trachoma school children take the disease into the school with them, and in Italy Maggiori states that measures are taken to isolate and treat the children before they are of school age. Selenkowsky in Russia, others in Palestine, as well as ophthalmologists in the Baltic countries, state that their experiences were practically the same; that the children were infected before they came to school, and that the younger children are infected mostly by their brothers and sisters. On the other hand it is interesting to note that while very few emphasize the significance of school infection, yet it is a thing we cannot deny, but the rôle played by the school in spreading the disease is not so great as was formerly believed.

As concerns the mode of contamination, this is generally by direct contact, and this danger may be increased through workmen, or others, who enter from countries in which there is much trachoma. Toilet articles in common use may be conductors of the infection, but it was not thought likely that dry objects, such as tools, had much to do with the spread of the infection. In many southern and eastern countries, especially Egypt, it has been a popular conception that flies may carry the disease, but the view was expressed that while this seemed to be true as regards the secondary infections, and not proved as regards trachoma itself, it cannot be denied, especially as concerns the acute cases. As regards the secondary infections, endemics are pos-

sible without them, as has been proven in the Baltic countries and in Russia. It appears that the dryness of a climate, although not a principal factor, plays its part in the spreading of the disease. Traffic has also a rôle, as shown in the increase of the disease at Marseilles, and the general increase during the World War; and the number of cases noticed at crosspoints of traffic in Africa. It was pointed out, however, that the most rigid immigration control will never completely eradicate the disease in a country where it is endemic. Neither would it have much result between two countries which are affected. It has, of course, value for those countries which are little infected. The decrease of trachoma, in high altitudes, may be particularly, or entirely, due to the fact that in these regions there is much less traffic.

As regards the eliminating of trachoma and its prophylaxis, while the situation was regarded as a terrible one, the view was expressed that there is no reason for too pessimistic an outlook. Even between Egypt and Palestine, the most infected countries, the fight against this disease does not seem to have much effect.

We next come to the consideration of measures advocated for the control and eradication of the disease. The control of national frontiers may of course be of great value from the international standpoint, but is only of personal value when it induces the sufferer to submit to treatment. Legal measures demanding compulsory notification have value, if carried out, for the prophylaxis is only of direct use when this leads to treatment. On the other hand, when the fear of notification stops the sufferer from consulting an oculist, it does more harm than good.

As stated, it has become a well-established fact that trachoma patients are, as a rule, already infected in childhood, and it is also pointed out that treatment in the early stages of this disease brings about the best results. Thus, the examination and proper treatment of school children appears to be the best method to combat and prevent the disease. It was pointed out that exclusion from school and segregation in schools and special classes without treatment have not proved efficient measures, in view of the great influences of family as regards the spreading of the disease. The examination and treatment of recruits has also been effective, but here also results are better if the treatment is started at an earlier age. It is unanimously agreed that in the infected countries there is a dire need for more physicians, more oculists, and more hospitals. General hygienic measures, as cleanliness and good housing, are important, but these are only too often beyond the power of the oculist to influence, and the same may also be said regarding the betterment of general welfare. Scientific investigation is important, especially as concerns the micro-biological etiology of trachoma and the diagnosis of incipient forms, and the relation of trachoma to certain forms of conjunctival folliculosis.

The importance of international collaboration was recognized and thought to be absolutely necessary. Every country in which the disease is prevalent and endemic is a source of danger to its neighbors. Frontier controls interfere with communication, and give only relative results. For this reason it is clear that countries free from trachoma should interest themselves in the fight against this terrible disease ravaging their affected neighbors. In this way they may remain free from infection themselves, while at the same time helping those who are suffering. That most of the countries affected are also the poorest, is an outstanding reason in itself for international intervention and help.

To accentuate the terrible grip of trachoma upon the human race, I shall give a few figures strikingly illustrating this. Almost every aspect from which we view the subject of trachoma is important, and that related to its wide distribution is not alone interesting but severely alarming. Except in some sporadic instances, we are not, in our country (America), confronted with the disease to such a degree as to give us a true measure as to the frightful and serious menace it is to the world as a whole. To give some idea of these startling aspects, we will turn to the extensive reports presented at the International Congress. These will show you that the problem is not only a very serious one but one that is truly international. It is important for those nations afflicted to improve the conditions, but it is also quite as important for other nations less affected to have the disease stamped out in the affected areas as a matter of self-protection. It is thought that the number of trachoma patients in proportion to other eye disease in ophthalmic clinics presents a fairly reasonable index as to the amount of the disease in that country

or community. Thus indicating the number of eye cases by the numerator (b) and the population index by the denominator (a), we have a frequency index of b/a. On this basis we find that in the countries in which trachoma is more frequent the disease is found in about one-third of the population, ranging from 4 to 5 per cent, to as high as 80 per cent. In Finland, in 1900, using this index somewhat modified so that the population index is (a) and one-third of the index of trachoma among eye cases is (b), we find there was 15 per cent. In 1928 this had diminished to 4 per cent. The conditions elsewhere are strikingly different. At present, in the Baltic provinces, we find in Esthonia 10 per cent, Lavonia 15 per cent, and in Lithuania 22 per cent. In Cochin China, it is 38 per cent, and in Palestine 16 per cent. In Syria we have the startling index of 80 per cent and almost as great in Lebanon of 76 per cent. In the Argentine we have 41 per cent, in Japan 28 per cent, in Formosa 40 per cent, and in Corea 16 per cent. Surely, these figures are sufficiently alarming to cause us to grasp the world significance of this disease. A general survey presented to the Congress, showed that in Italy the recruits had trachoma in 8.84 per cent, with a maximum in those from Sardinia of 56 per cent. The school statistics showed that this disease is greatly spread among the school children, from 10 to 12 per cent in some places. In some areas a marked diminution has occurred under the influences of measures taken for combating the disease. The disease is more frequent in the great industrial centers and at the large ports; and the immigrants entering play a large part in spreading the disease. The nature of industry is of secondary importance, and there are 80,000 sufferers from trachoma under supervision in Italy. In Tripoli, there is about 25 to 80 per cent of the population affected with this disease. In contrast to this, in Belgium there has been a gradual decrease, so that there is now but from 0.5 to 1 per cent of persons examined who show trachoma. In Rumania, the reports of Malonesco and Panikscu, and others, showed a great increase in trachoma since the war, especially in Transylvania. In the clinic at Bucharest the eye patients treated for this disease have increased from 10 to 20 per cent. The disease is more frequent along the Ukranian frontier and the total number of trachoma cases in Rumania is estimated at about 90,000, of which only 11,000 are under medical treatment. Maiewsky reported that in Poland, in some localities, all of the school children are trachomatous, especially among the Jewish population, and the war did much to spread the disease. Examinations in Warsaw give figures of between 10 per cent and 100 per cent. In Czecho-Slovakia, Bruckner reported that out of 13,000,000 population, 61,000 suffer from this disease.

However, these reports, alarming as they are, do not so deeply impress us as the report of Prof. Selenkowsky of Leningrad, as well as those from Palestine by Ticho; the latter we will consider first. In Palestine there are about 400,000 trachoma patients, 15 per cent of the Jewish population, and 50 per cent among the Arabian. The frequency rapidly increases from the third to the fifth year of life, but remains stationary until the eighth year, and then gradually decreases to the twentieth. Ticho states that the children are already infected before they come to school, and that infection in the school is rare. More boys than girls are affected in the proportion of 4 to 3. More children from the country are affected, than from the towns. In explanation of this apparent paradox, probably the explanation is found in that in the small towns of the country health supervision and the general surroundings are not so good as in the larger towns with more official administration. He states that the temperature has an indirect influence by furthering acute purulent conjunctivitis in the hot months. In 26 per cent of the blind in Palestine the cause is found in trachoma. We will now briefly consider the report of Selenkowsky. Russia is an incomprehensible territory with different geographical features, different populations, with different cultures and methods of living. In European Russia, with a population of 113,000,000, there are known 767,306 cases of trachoma, or 144 for every thousand of the population. In Asiatic Russia, of a population of 11,000,000, there are 124,062 of the population affected, or 90 for every thousand; in the Caucasus 58 in every thousand; in Siberia 45 in every thousand. The industrial circles are affected less, and the borderlands and cities are affected more. Selenkowsky believes that it is not probable that an immunity is present in the adult, and also that there is not a special susceptibility in the child's conjunctiva. The disease does not seem to be racial in its manifestations, but rather it is to be found that the extension is

largely concerned with the immediate or indirect surroundings of individuals. It does not appear as much in favorable localities as in villages situated near swamps and those that have few trees or forests. In final analysis, it seems that the disease is one intimately related to living conditions, both in its origin and its extension. In the upper classes of society—the more cultured—there is comparatively little of this disease, but in the lower classes, living under most unfavorable hygienic conditions, we find it common. This writer believes that trachoma is not extended through the school, but that it usually occurs at home, and from here is brought into the school, and that we must therefore consider it from a standpoint of attack of a childhood disease that must first receive proper attention in the home.

Thus, from an enormous amount of material presented at the Congress, the writer, from notes taken at the time, through the process of his own memory, and by references made to the reports, has attempted to present certain vital aspects of an important world problem. Certainly enough has been presented to indelibly force upon us the menace of trachoma. There can be no doubt that it is as much a world problem, and quite as important as the world fight against tuberculosis, lues, and other infectious and epidemic diseases. Every possible point of entry into our land should be guarded; and, of course, much has been done and is being done now in this regard. Sporadic manifestations of the disease should be treated by intelligent and competent health officers and ophthalmologists. All cases of an individual sporadic nature should be reported and treated immediately and kept under supervision. We must keep in mind that the disease finds its more fertile soil in unclean habits of life and unhygienic surroundings. While we are not generally, or severely, afflicted in the United States, the disease should nevertheless receive the most thorough attention, both from the state, health officers, and ophthalmologists. There is another aspect of the question that concerns international relationship. Not only should we attempt to stamp out the disease entirely from our own country, but we should be willing to help the less favored countries thus afflicted, by all the means we have at our possession. This is not only from the correct humanitarian standpoint, but it is vitally necessary for the protection of both ourselves and our neighbors. As stated, very little was said at the Congress regarding treatment, and probably for the reason that there is a very general agreement upon the different forms of this throughout; proper surroundings, prophylactic measures to prevent its spreading, avoidance of contact in the immediate family and inner circles, and the use of local medication. The writer remembers, while talking with Prof. Fuchs some time ago regarding this disease, that the latter told him that among all the different medicines tried in Vienna, none seemed to be so efficacious as copper sulphate. The writer of this article, while frequently using this in the form of the copper stick, supplements it by a few drops of a 5 per cent solution of copper sulphate in glycerine, dropped into an eye cup half filled with distilled water, in the eyes morning and night, by the patient at his home. Silver may at times be alternated, but ofttimes irritates more than it does good. It seems to be better in its effects in very acute phases, and for the manifest reason that the superficial layers of the conjunctiva are markedly affected by it and are thrown off. Tannic acid in glycerine is also a very efficient drug to alternate with copper sulphate. It is also very important, as in all inflammatory conditions of the conjunctiva with much secretion, that a bland unguent such as petrolatum or alboline be smeared along the palpebral borders before the patient retires. This prevents retention of materials during the night. These therapeutic suggestions are simply from personal experiences of the writer himself, and not reflections from the Congress.

Roche of Marseilles, in a report concerning the clinical studies as to infection in cases of trachoma, states that these lead to two references:

1. For the carrying of trachoma to others, an intermediary (a host) or additional factor, is necessary. The greater or lesser profusion of that coöperating factor would determine the greater or lesser frequency of the infection. This explanation is not very plausible, though it cannot be excluded with certainty in the present state of our knowledge.

2. Trachoma is only infectious during a short period. If this supposition should be confirmed by clinical or experimental examination, this would, as a matter of course, greatly simplify the combating of trachoma. It would be sufficient to isolate the patients during the period of infection in order to prevent all spreading of the affection.

MALARIA AND ANOPHELINE MOSQUITOES IN MINNESOTA

William A. Riley
Department of Zoology, University of Minnesota
Minneapolis

IT is very generally believed by medical men, and by others interested in public health, that malaria cannot originate in Minnesota. The idea is not supported by the facts and though the local appearance of the disease is very exceptional the possibility of sporadic cases should be recognized.

During the summer of 1929, Dr. O. McDaniel, of the State Board of Health, called the writer's attention to a case of clear-cut local origin in the practice of Dr. A. E. Meinert of Winona. The patient, a city fireman, had not been out of the state in five years' time and had not been sick before. Blood smears showed heavy infection with benign tertian malaria.

Sanford (1913) reported another case clearly acquired in Minnesota. It was that of a child two years of age, whose residence and birthplace was Oronoco, Olmsted County, and who had never been out of the state. Blood examination revealed a double infection of the tertian parasite, with many typical specimens of *Plasmodium vivax*.

He also reported a typical case of malaria in a woman of 35, who was born in Michigan, had lived for many years in North Dakota and for the three years preceding examination, in Wisconsin. He states that Dr. L. F. Germain had reported before the Milwaukee Medical Society two cases of malaria clearly contracted in Wisconsin during the summer of 1911. Coon and Overton (1923) refer to six imported cases which had been treated in the infirmary of the University of Wisconsin, at Madison. Discussing the possibility of locally acquired infection they cite three cases which had occurred in the practice of other physicians.

Doubtless there are a number of other cases in both Minnesota and Wisconsin which have come to the attention of practitioners and have not been reported. The infection may even be completely unrecognized because of the belief that malaria does not occur in the state.

An instance in point came to the attention of the writer several years ago. Following a tonsillectomy a patient in one of the hospitals of the Twin Cities exhibited a considerable rise in temperature which was the occasion of some concern until he himself suggested that he had malaria, a disease which he had previously suffered from in his southern home. Blood examination showed that this was the cause of the fever, a latent infection which had been stirred up by the operation.

Similarly, students returning to the University after summer vacations spent in the West or in the South occasionally exhibit an acute attack of malaria remote from the source of infection, or summer tourists may suffer a relapse of the disease while camping in Minnesota.

Of course, cases such as those cited above could not give rise to endemic infections in the absence of mosquitoes capable of carrying malaria. The significant fact is that we have in Minnesota two species of Anophelines, both of which are demonstrated transmitters of the disease. *Anopheles punctipennis*, a vector of both tertian and æstivo-autumnal malaria is fairly common in the Twin Cities. I have taken it repeatedly in the buildings of the State University. C. W. Howard, 1916, has had the same experience, and reports for Savage, Minnesota, as well. Evidently this is the same species reported by Taylor, 1910, under the name *Anopheles maculipennis*.

Anopheles quadrimaculatus, the potential carrier of all three types of the disease, has likewise been taken repeatedly at St. Paul and there is in the University collection a specimen labelled Grand Rapids, Minnesota.

According to Sanford, 1913, "In 1903, Dr. H. P. Johnson, then Professor of Bacteriology in St. Louis University, noted the presence of numerous Anopheles mosquitoes in the vicinity of Ely, Minnesota." There is no indication as to species, but in all probability they were of one of the above-mentioned.

With the increasing tourist influx and especially with the establishment of our numerous tourist auto camps, the possibility of infection

of Anopheles mosquitoes is by no means a remote one. According to the report of the "Ten Thousand Lakes Association" it is estimated that more than one million, six hundred thousand tourists visited the state during the summer of 1929. In each of the 381 recorded tourist camps there was an average number of 33.27 persons staying daily. This would give a total daily number of 12,675 staying at these camps scattered over the state. Many of these came from malarious sections of the country and doubtless a significant number are actual carriers of the parasite. The writer several years ago made an examination of a group of twenty young men who had come to Minnesota from Arkansas and found two of them to be malaria carriers.

Moreover, with the increasing use of induced malaria in the treatment of paresis there is an additional very definite possibility of mosquito infection and subsequent transmission. The idea that the organisms from these patients are not capable of developing the parasite cycle in the mosquito is altogether fallacious.

That isolated carrier cases may become foci of local outbreaks has often been established. Craig (1909) points out that, "Local epidemics of malaria are often observed in places which may have been free from infection for many years. An instance of this kind occurred under my observation in a city in Connecticut. Some years before the Spanish-American war this city occasionally reported the presence of tertian malarial fever, but the cases were few in number and no other form of malaria was ever observed. After the return of a company of militia at the close of the war mentioned, several cases of remittent fever were observed which, upon investigation, were found to be infections with the æstivo-autumnal malarial plasmodia. The introduction of this organism was traced to returning soldiers, some of whom had suffered from this form of malaria while in Cuba upon special service. In this instance the conditions necessary for the spread of the disease were all present in the city with the exception of the infected individuals, the right species of Anopheles, warmth and moisture, a susceptible people awaiting only the returning soldier infected with the æstivo-autumnal plasmodium, and thus a form of malaria never before observed in the State of Connecticut became prevalent in this city."

It is significant that early records show that "ague" was commonly present in Minnesota during pioneer days. Making due allowance for imperfect diagnosis, it is obvious that the disease was brought in repeatedly from malarious regions, prevailed for a time and then, since conditions for its continued propagation were unfavorable, it pratically disappeared. These unfavorable conditions were largely climatic, since Minnesota lies about at the northern limits of the distribution of the disease in the United States. This limit, according to Hirsch (cited by Marchiafava and Bignami, 1900), is between the isothermal lines of 15° and 16° C. (59° and 60.8° F.), mean summer temperature. The United States Weather Bureau shows that for twenty years the entire state had a mean summer temperature slightly above 60° F.

The conditions outlined make it certain that sporadic cases of malaria in Minnesota are to be reckoned with. That they will ever be common is quite out of the question. Climatic conditions, the short season, with its relatively small population of anopheline mosquitoes, together with the remote mathematical possibilities of just the right combination to insure transmission, all preclude possibility of more than rare cases.

CASE REPORTS

CONGENITAL VALVULAR OBSTRUCTION OF THE POSTERIOR URETHRA

REPORT OF A CASE

RICHARD B. HULLSIEK, M.D.*
Saint Paul

The occurrence of abnormal folds or valves in the male posterior urethra causing varying degrees of urinary obstruction is now recognized as a pathological entity. Tolmatschew, in 1870, gave the first complete discussion of the subject, while Eigenbrodt, in 1891, probably discovered the condition for the first time in a living subject, upon whom he was operating for an obscure urinary obstruction.

Knox and Sprunt, in 1912, were the first to report a case in America. Young, in 1913, however, made the first clinical diagnosis of the condition and corrected it surgically with a successful result. Young, Frontz and Baldwin in 1919 collected from the literature twenty-two cases of congenital valves of the posterior urethra. These were cases found at autopsy. In the same article were reported twelve cases seen in the urological and pediatric clinics of the Johns Hopkins Hospital. In eight of the latter cases diagnosis had been made clinically and successful surgical procedures instituted for the removal of the obstruction. The other four cases in this series were not operated on, and died. In 1925 Hinman and Kutzmann, in a comprehensive review of the subject, reported twenty-one additional cases, six of which were observed in their personal practices, thus bringing the total number of cases reported to date of congenital valvular obstruction of the posterior urethra to fifty-six.

Young, Frantz and Baldwin have described three definite types of the anomaly. The first type is characterized by a ridge-like fold extending downward from the verumontanum and dividing into two membranous sheets. The outer edges of these sheets attach themselves to the rectal, lateral and pubic walls of the urethra as they extend distally; the inner or free edges may or may not unite below. In some cases of this type only a single unilateral valve is present. In the second type a ridge similar to that of the preceding type is found, but it passes upward from the verumontanum and divides into two valve-like folds which attach to the urethra just outside the vesical sphincter. The third type is a more or less disc-shaped valve, the outer edge of which is attached to the entire circumference of the urethra; a small opening toward its center prevents complete urinary obstruction. The latter variety of valve may be found in any portion of the posterior urethra and bears no relationship to the verumontanum. The valves in the following case are similar to those described in type one.

*From the Department of Urology, the Miller Clinic.

CASE REPORT

E. B., age three and a half years, male.

Complaint: difficult painful micturition, abdominal distention. Swelling of face.

Family history: Irrelevant.

Past history: Normal delivery. Breast-fed fourteen months. Chickenpox, measles and occasional "colds."

Present illness: The mother states that since birth there had been noted severe straining to empty the bladder, but for the past two months patient has cried whenever he urinated. He would strain, stand on his toes and finish the act by bending over and grasping the lower abdomen. Circumcision was done elsewhere five weeks ago, without benefit. Within the past month straining at urination became more marked and there was a protrusion of the rectal mucosa through the anal sphincter whenever micturition was attempted.

Since the onset of the dysuria there has been marked frequency and urgency of urination day and night, with the passage of only small quantities of urine. The stream has been slow in starting, with poor force and sudden cessation while straining. During the week prior to admission to the hospital a swelling of the face was noted, together with the appearance of reddish spots on the body.

Physical Examination: The patient is a boy three and a half years old, well developed, but sallow and appearing very ill.

Head and neck. The left eye shows recent hemorrhage beneath the sclera.

Throat. Negative. There is marked distention of the anterior jugular veins.

Thorax. Heart and lungs, negative. Pulse 110, regular. Temperature 100.2°.

Abdomen, distended. There is an ovoid tumor rising from the symphysis to well above the umbilicus.

Skin. Pale, with pinkish, red hemorrhagic spots on the lower abdomen and thighs. The superficial veins are very evident. The child is irritable, cries much of the time, and is apparently having marked lower abdominal distress.

External genitalia, normal.

The urine voided during the examination is grossly bloody.

Laboratory Data: Blood, hemoglobin 60 per cent. Red blood cells 3,540,000. White blood cells 14,650. Polymorphonuclear leukocytes 73 per cent, lymphocytes 27 per cent. Bleeding time, one minute, 25 seconds. Coagulation time 4 minutes.

Urine—specific gravity 1.008. Reaction acid. Albumin heavy cloud. Sugar negative. Microscopic—numerous leukocytes, clumps of pus. Many red blood cells.

Blood chemistry—Sugar 125 mgs. Creatinin 2.50 mgs. Urea Nitrogen 56 mgs.

The renal function was not determined because of

the distended bladder, which was to be decompressed.

X-ray—A cystogram (Fig. 1) shows the bladder outline irregular, trabeculated, with small cellules, and a dilatation of the bladder neck and posterior urethra. There is reflux up both ureters showing dilatation even though no attempt was made to force a large quantity of the opaque media into the bladder.

Cystoscopic Examination—This was preceded by preparatory catheter treatment. Buerger cystoscope (F. 16) inserted without difficulty. The bladder wall showed marked trabeculation. Numerous small cellules were seen. Both ureteral orifices were dilated and similar in appearance to large diverticulæ. The prostatic urethra was dilated, as was the internal sphincter, allowing easy manipulation of the cystoscope and inspection of the verumontanum. The superior crista appeared normal. The inferior crista showed redundant folds of mucous membrane, semilunar in shape, swinging downward and laterally, in a fan-shaped manner, with the apex at the verumontanum. These folds were

Fig. 1. Cystogram showing dilated posterior urethra and reflux up both ureters.

flattened by the cystoscope, but with a small urethroscope improvised from a trocar these folds could be seen to balloon out with the egress of fluid from the bladder.

Treatment—A cystotomy was performed. A thickened, trabeculated bladder was seen. The ureteral orifices were dilated sufficiently to be palpated. The posterior urethra and vesical sphincter were dilated, permitting the palpation of the valves on the end of a sound which had been caught in the pouch beneath. Division of the valves behind the end of the sound was carried out.

The patient made a slow recovery, and finally became afebrile. Gradually the pyuria disappeared, and the general condition rapidly improved. The urethra was dilated several times following the operation and he was voiding normally before leaving the hospital. He was seen two and one-half years later and appeared normal in every way.

PHARYNGO-ESOPHAGEAL MEDIASTINAL FISTULA REËNTERING THE ESOPHAGUS*

REPORT OF CASE

HERMAN J. MOERSCH, M.D.,
Division of Medicine, The Mayo Clinic,
and
E. STARR JUDD, M.D.
Rochester, Minnesota

Mediastinal abscess, perforated blood vessels, and esophago-tracheo-bronchial fistula are some of the complications that may arise from ulceration as the result of an impacted foreign body in the esophagus. It is therefore imperative that all foreign bodies lodged in the esophagus should be removed as soon as possible, since perforation may take place in a short time, especially if the foreign body is large and has sharp edges.

Recently, a patient was observed in the clinic who demonstrated the rapidity with which perforation may take place, and who also presented one of the most unusual of complications, pharyngo-esophageal mediastinal fistula.

The patient, a middle-aged woman, a year preceding admission to the clinic, had choked while eating chicken, and felt the sensation of a bone sticking in her throat. Considerable pain and dysphagia followed. Nothing was done until the third day, at which time the patient felt very ill and uncomfortable, and esophagoscopy was advised. This failed to reveal the foreign body. The patient stated, however, that she thought she felt it pass down the esophagus and into the stomach just preceding the examination. The patient became progressively worse, and high fever and stupor developed. Evidence was found of a mediastinal abscess, which was drained on the tenth day through the left supraclavicular region, with excellent results, the patient recovering promptly. The dysphagia, although slight, persisted, and the wound in the left supraclavicular region continued to drain a small amount of mucoid material. In spite of further surgical interference, the sinus persisted although it drained very little. Approxi-

*Submitted for publication April 11, 1930.

mately every four or five weeks since the onset, the patient had experienced a sense of substernal pressure, malaise, slight elevation of temperature and an increase in dysphagia. Two or three days later, the sinus in the left supraclavicular region would usually open and discharge mucopurulent material for two or three days, it appeared to come in contact with a fluctuating mass. The following day the sinus in the left supraclavicular region opened and drained spontaneously. Roentgenologic examination following drainage revealed a sinus discharging from the bottom of the pharyngo-esophageal diverticulum into a large mediastinal pocket, with

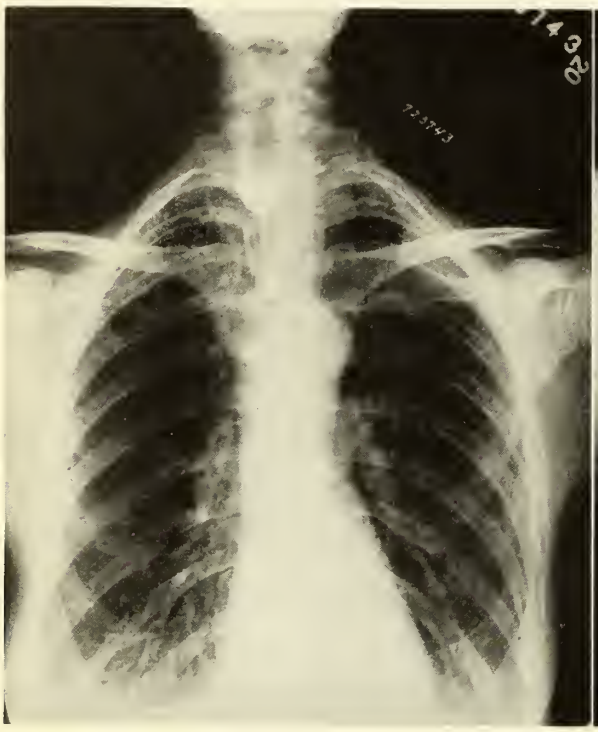

Fig. 1. Esophagus before discharge of material retained in mediastinal sinus.

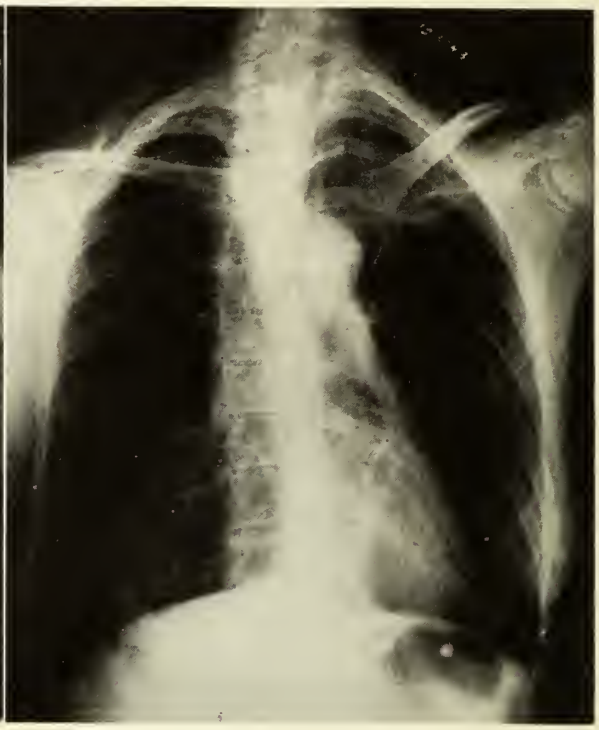

Fig. 2. Esophagus after drainage of mediastinal sinus.

which relieved the symptoms. During the time of drainage, small amounts of food that had been eaten would be discharged through the sinus. If the sinus in the left supraclavicular region did not open and drain to terminate the attacks of malaise, fever and dysphagia, the symptoms were relieved by something giving way in the thorax and discharging into the esophagus.

The foregoing cycle had repeated itself with great regularity, and at the time the patient presented herself at the clinic she felt such an attack developing.

On examination, the sinus at the base of the neck was dry, and very small. In swallowing, the patient made a peculiar noise, which is characteristic of pharyngo-esophageal diverticulum. Roentgenologic examination revealed a pharyngo-esophageal diverticulum (Fig. 1) with a small amount of barium lodged about the level of the arch of the aorta. On esophagoscopic examination the diverticulum was found filled with mucoid material, and there was obstruction in the upper third of the esophagus, which gave the impression of being due to an extrinsic mass. The passage of a number 41 French sound over a previously swallowed silk thread also demonstrated the diverticulum and the obstruction in the upper part of the esophagus. However, a number 45 French sound was passed with ease; a fistulous tract leading from the pocket to the left supraclavicular region, and another burrowing down the posterior mediastinum and emptying into the middle third of the esophagus (Fig. 2). Fluoroscopic examination disclosed that about equal amounts of barium passed down the esophagus and the sinus tract.

Apparently, the attacks of malaise, fever, dysphagia and substernal distress were the result of the tract emptying into the esophagus and becoming obstructed. The material accumulated in the mediastinal pocket until it was either discharged through the sinus to the outside, or into the esophagus, with relief of symptoms.

Undoubtedly the sequence of events in this case was the lodgment of a piece of chicken bone in the pharyngo-esophageal diverticulum, with perforation into the mediastinum and subsequent mediastinal abscess. Whether the bone went through into the mediastinum, or later was discharged into the stomach, is difficult to determine. The abscess was drained through the left supraclavicular region with the formation of a sinus tract, and the third opening into the middle third of the esophagus was undoubtedly spontaneous, although it may have been due to the foreign body burrowing its way back from the mediastinal pocket into the esophagus.

It was impossible to isolate the sac of the diverticu-

lum, and an attempt to remove it was not made. The fistulous sac was dissected out and excised. After the mediastinal sac had been drained and the sinus had filled in until it was small, the esophagus was dilated repeatedly. This seemed to give relief. When the patient was dismissed from observation she was apparently in good condition but we advised that the dilatations of the esophagus be continued.

INCORRECT LABELING OF UPSHER SMITH DIGITALIS PREPARATIONS

Tablets Folia-Digitalis (Upsher Smith) 1 grain, Tincture Digitalis (Upsher Smith) and Capsules Folia-Digitalis (Upsher Smith) 1 grain, were exempted by the Council on Pharmacy and Chemistry as having the status of official substances. The Council reports that a committee for the study of the actions of digitalis in patients suffering with pneumonia used tablets of digitalis Upsher Smith and tablets of digitalis of another firm and directed that patients receive these in uniform doses calculated to induce a moderate degree of digitalization, assuming that both specimens of tablets were correctly labeled; that after a total of 258 patients had been treated it was discovered that the tablets of digitalis Upsher Smith induced both severe and minor toxic symptoms far more frequently than those of the other firm, and that an examination of the records brought out that minor toxic symptoms were more than ten times as great in those who received the Upsher Smith tablets as in those who received the other firm's tablets and that the mortality was 49 per cent of all cases of pneumonia treated with the first, as compared with 38 per cent in all those treated with the other tablets. The Council further reports that both brands of tablets were then assayed; that the tablets of the other firm were found to be of activity stated on the label, and those of Upsher Smith to be twice the activity stated. Upsher Smith has assured the Council that any of his misbranded preparations on the market will be called in, and that in the future the greatest care will be taken to insure that the potency of these will be stated correctly. (Jour. A. M. A., April 26, 1930, p. 1305.)

THERAPEUTIC CLAIMS FOR THEOBROMINE AND THEOPHYLLINE PREPARATIONS

The Council on Pharmacy and Chemistry reports that, questions having arisen in regard to the advertising claims that might be permitted for the xanthine derivative preparations accepted for New and Non-official Remedies, the Council's referee for these products presented a review of the important literature, with special reference to the value of xanthine derivatives in vascular hypertension and arteriosclerotic conditions. In the light of this review, the Council decided that the following claims could be permitted for both theobromine and theophylline: (a) diuretic action; (b) myocardial stimulation; (c) occasionally (and more often with theophylline) relief of pain in angina and similar lancinating pains. It does not seem permissible to claim lowering of hypertension. (Jour. A. M. A., April 26, 1930, p. 1306.)

ANNUAL MEETING OF THE COUNCIL ON PHARMACY AND CHEMISTRY

The Council on Pharmacy and Chemistry held its annual meeting at the Association headquarters March 7 and 8. Extended consideration was given to the work of the newly established Committee on Foods and the proposed publication of the book "Accepted Foods." The progress made appeared satisfactory and the work appears to be appreciated by the profession, the public and manufacturers. The Council discussed the status of the streptococcus preparations for the treatment of rheumatic fever made in accordance with the method of J. C. Small: it was the consensus that, while these products are suitable for controlled investigation by qualified experimental workers, propaganda which invites their general use is not justified at this time. The Council decided that the available evidence does not demonstrate the usefulness of puerperal fever streptococcus serum. The Council decided to continue the acceptance of Type I antipneumococcic serum for New and Non-official Remedies; that Type II serum is still in the experimental stage; and that pneumococcic serum preparations representing a mixture of Types I and II pneumococci be considered unacceptable. It was decided that, while adequate clinical evidence for the potency of a liver extract must be required before acceptance, further clinical testing will not be required after a product has been shown to be active and the method of preparation shown to be satisfactory. The Council considered the rules that are to govern the use of the seal to be used by manufacturers to identify products accepted for New and Non-official Remedies or for Accepted Foods. The Council approved a proposed study of commercial allergic protein preparations and offered coöperation. The Council considered a proposed manual for the guidance of hospitals to be prepared by a committee appointed by the Council on Medical Education and Hospitals with the coöperation of the Council on Pharmacy and Chemistry. Plans for the consolidation of various committees concerned with anesthesia were discussed. (Jour. A. M. A., March 22, 1930, p. 874.)

POTENCY OF ARSPHENAMINE

There is no official standard for therapeutic potency of arsphenamine preparations. According to reports of the United States Public Health Service Hygienic Laboratory, no one brand has been definitely established as superior to others when considered from the point of view of clinical efficiency. In some foreign countries, every preparation of arsphenamine and neoarsphenamine is tested on mice for therapeutic efficiency before being used. (Jour. A. M. A., November 9, 1929, p. 1495.)

President's Letter

NOT at all infrequently some one asks the question, "How shall I choose a good doctor?" One may answer, giving many rules of guidance of more or less doubtful value, the while a still, small voice within whispers the query, "What *is* a good doctor?" Surely we must know something of what enters into the making of a good doctor before we can tell a person how to make a wise selection. Without making any attempt to answer the question it is permissible to cogitate.

Youth finishes his interneship, receives his diploma from a Class A school of medicine, successfully meets the requirements of the laws of the state in which he decides to open his office and goes to work. If he has given reasonably faithful attention to his duties before entering upon the practice of his profession, it is safe to say that he is in a position to give intelligent attention to such cases of illness as may come his way. He has abounding hope and energy. His optimism is contagious, his energy appeals, his pleasing personality attracts. Directly he is busily working, is riding a wave and surely floating to its crest.

When youth opened his office he was not a good doctor as yet. He had but started to explore the field of *experience* now opening before him. He is about to learn to be a doctor. The element of *time* now enters the equation, without which experience may not be had. What his experiences are, what they will mean to him, will depend largely upon what he does with the time he is using. If he has wisdom as a reasonably well developed attribute his time will be spent (excepting such as is justly his for rest and recreation) in carefully recording his observations, classifying his records, comparing them, thinking of the significance of his findings. Thus knowledge born of experience will grow. His *judgment,* a final and deciding factor in the making of a good doctor, will have ample opportunity to develop. If he possesses that keen discriminatory quality which we call good judgment he is well on the road to becoming a good doctor.

But the years are passing and youth is slipping away into maturity. At some point along the way the lines of life diverge. One leads to lost interest, indifference, self-satisfaction, professional mediocrity, or less, and a flabby minded old age unless death mercifully intervenes. The other leads into fresh and increasingly interesting fields. It gives breadth of understanding, it enhances the value ofexperience, it fixes firmly in the mind the lessons learned through observation and study. This line of life is marked by an insatiable thirst for knowledge. It compels him who follows it to seek for the knowledge and tales of experience of his fellows. In season and out he cries for more. This line leads him to his local medical meetings, to the state meetings, to such of the special meetings as his taste dictates. Staff meetings, if available, he surely attends. He will make flying trips to medical centers where he may spend a profitable hour with some great clinician, or at a pathological conference or an *x*-ray demonstration. Perchance he may have quiet converse with some learned mind for a little time. Thus he adds to his knowledge, makes his experiences mean something, ripens his judgment and gets zest and inspiration with which to continue his labors.

From this picture we may see clearly that work, work of the right sort, returns rich dividends in knowledge and skill and mental and moral satisfactions. As work of this sort may be done in small and out of the way places as well as in the great cities it is reasonable to suppose that "professional ability is pretty evenly distributed over the country, reputation is largely a matter of chance."

Departing from the field of cogitation to matters of fact it may be stated that in making up the scientific program for the July meeting of the State Society the committee in charge wrote letters to all members asking them to express their choice of subjects for a series of six symposia. An amazing number of answers were received. A great variety of subjects were named. The Program Committee merely acted as a clearing house for the profession at large which chose the following subjects:

1. Traumatic Surgery.
2. Carcinoma. The request here was that the most recent etiological factors together with early diagnostics be stressed.
3. Rheumatic Fever. The men appeared to be aware of new developments concerning rheumatism and expressed a wish to learn the latest.
4. Anesthesia. Clearly the profession is interested in all modern methods. Succinct definite and correlated information will be given.
5. Therapy. This subject was almost universally requested.
6. Our State Institutions. A large number of people, both lay and professional, desire to know how to get persons in and how to get them out; what is done for the inmates and how they get along. The profession evidently feels that the fine body of men in charge of these institutions are members of the profession and better acquaintance is desired.

Judging from the great flood of letters received by the Program Committee practically the entire membership of the State Society classifies for cogitative life line number two. On that basis the Duluth meeting will be immense.

S. H. Boyer

President,
Minnesota State Medical Association.

THE MINNESOTA MEDICAL SCHOOL AND THE JULY KIDNEY SYMPOSIUM*

There is a rather brief announcement in this Journal in the May issue (page 335) of this most noteworthy educational step, planned and executed through our Professor of Medicine, Hilding Berglund. This extraordinary assemblage of men from near and far, who have made names for themselves in medical science and have noteworthy contributions to discuss in the special field pertaining to normal and abnormal kidneys, is a unique evidence of Professor Berglund's wide acquaintance and the confidence these men have in him. It is likewise an evidence of the high position in medicine granted both to our own state and its university, because these men do not casually abstract this precious time from the very best portion of their summer vacation periods.

This set of lectures is going to draw together those interested from near and far. To some, uninitiated, it may appear that the field of kidney physiology and pathology is singularly limited, and that a greater variety of subjects should be discussed. With this contention few will agree.

In the first place we might paraphrase the remark of the old teachers who said, "He who understands syphilis thoroughly in all its manifestations understands all disease." So let us say in particular that the kidney is capable of study from the widest angle of approach; it is pivotal among organs; its blood supply and its anatomical position as well as its avenues of excretion provide easy isolation. When Professor A. N. Richards, for example, demonstrates to us his superb work on kidney capillaries and their distribution he is virtually introducing us to the body capillary bed as a whole. A full knowledge of kidney physiology would mean a long step toward knowledge of the body as a whole.

We have all talked about kidney classifications and the name of Volhard comes first to mind. Many might find it disconcerting whether to place him in the time of Harvey or Virchow. It will be as comforting as impressive to see him in the living—and incidentally observe the distance he travels to be with us!

This sketch is something of a summons or challenge to our state of hibernation or inebriety. We must not sit purposelessly by, unaware of this great treat and opportunity. Let us give these men an audience; let us linger about the University on some of these days at least; let us not fail to show to Professor Berglund, the other University men and their guests our full appreciation of this evidence that our medical school has not only a commanding position, but an intense zeal to come into a position second to none.

E. L. TUOHY, M.D.

*July 7 to 18 at the University Medical School.

"JAKE" PARALYSIS

"Jake" paralysis has recently been given wide publicity in the lay press. Reports are that many have been stricken in Oklahoma, Kansas, Illinois and Massachusetts. The prime offender is Jamaica Ginger, which masquerades under the name of "Jake." Reports have it that it has been dispensed at soda fountains, soft drink parlors, and has even been "bootlegged."

A number of years ago weaker extracts of ginger were on the market, and a propensity for drinking them grew up in the prohibition states, and during the early days of national prohibition. However, even the so-called "Jake" addicts were unable to drink the U.S.P. extracts, with its 4 per cent of ginger. Manufacturers of extracts designing to meet this beverage demand, therefore, used only about one-half of 1 per cent of ginger extract, and made up the rest of the 4 per cent non-volatile matters by preparations which cannot easily be detected by the drinker, and which will pass a superficial test for solid content. Such adulterants as castor oil, other bland viscous oils, powdered resin, pine oil, tar and oleoresin have frequently been discovered. Lately creosol and phenol products have been discovered.

The exact nature of the poisonous product is as yet unknown. The probabilities are that it may be a higher alcohol. Clinically these cases resemble typical alcoholic polyneuritis, with partial, or complete, paralysis of the distal portions of the four extremities.

Jamaica ginger may be manufactured only under permit from the Bureau of Prohibition, but it is believed that many manufacturers make this sub-standard ginger to the order of distributors, who supply their own labels, and who are, therefore, free to resell the product to grocery stores and other vendors, practically free from Government interference, because the extract conforms to the Food and Drug Acts in label requirements, and apparently as to solid content. The Government is endeavoring to trace these products to their source of manufacture, and close them up if it cannot be shown that the adulterants were not added after the shipment left the manufacturer. That this has proved to be a difficult task is shown by the widespread appearance of another product of Prohibition—the so-called "Jake" paralysis. Just how serious, from a prognostic standpoint, this form of paralysis is, cannot be stated at this time. Neuritis resulting from "moonshine" has often been found to be very prolonged and disabling. It is probable that the same situation, or a worse one, will result from this unknown poison.

G. N. R.

UROSELECTAN

The newly developed iodine preparation known as Uroselectan promises to be of very material assistance in the diagnosis of kidney lesions. Being a stable iodine combination it can be given intravenously with slight chance of iodism resulting, and its excretion by the kidney visualizes the urinary tract in the *x*-ray film. Occasionally the patient experiences a general reaction with digestive disturbances, pain in the arms, etc., which may be due to delayed elimination or drug idiosyncrasy.

With the technic used at present the kidney, pelvis and first part of the ureter and the bladder may show up well in the *x*-ray. The middle and lower portions of the ureter evidently do not contain the opaque urine in sufficient quantity to render much information as to the condition of this portion of the tube.

It is evident that even with improvement in the present technic being tried out by urologists, this new method can never entirely replace cystoscopic examination. In instances, however, where cystoscopy is contraindicated or where ureteral catheterization is impossible, or the pelvis cannot be injected, uroselectan intravenously can give information not otherwise obtainable. In cases of hydronephrosis or hydroureter this newer technic should give conclusive evidence.

This new preparation may acquire a very important place by replacing the opaque solutions usually used to visualize the urinary tract. It is thought by some to be less irritating and promises to give just as clear-cut pictures as the iodide solutions now used.

It is to be hoped that the intravenous use of uroselectan will not prove to be simply another *x*-ray examination to be used indiscriminately. This is not likely, however, for it involves an intravenous administration and *x*-ray exposure at half-hour and hour and a half intervals, and does not give the last word regarding the state of the urinary tract.

The interested reader is referred to two abstracts on the subject which appear in this issue.

OF GENERAL INTEREST

Dr. Joseph Borg, Saint Paul, who is at present taking post-graduate work in internal medicine in Vienna, is expected to return July 1.

Dr. Walter D. Abbott, formerly of the Mayo Clinic, Rochester, is now associated with Dr. Harry A. Collins at 820 Equitable Building, Des Moines, Iowa.

Dr. E. De Witt Simpson has moved into his new offices at 401 Medical Arts Building, Minneapolis, where he is engaged in the practice of general surgery.

Dr. Donald C. Smelzer, for the past five years superintendent of the Miller Hospital, Saint Paul, has been appointed superintendent of the Graduate Hospital, Philadelphia, where he will take over his duties July 1.

The Minneapolis General Hospital is now offering a six months' technician's course in electrocardiography and medical photography. Information concerning the course may be obtained from the superintendent, Dr. Walter E. List.

The Samuel D. Gross Prize of the Philadelphia Academy of Surgery has been awarded by the Trustees to Dr. Emile Holman, Stanford University Hospital, San Francisco, California, for his essay on "Abnormal Arterovenous Communications."

THE JOHN PHILLIPS MEMORIAL PRIZE

The American College of Physicians announces the John Phillips Memorial Prize of $1,500.00, to be awarded for the most meritorious contribution in Internal Medicine and sciences contributing thereto, under the following conditions:

1. The contribution must be submitted in the form of a thesis or dissertation based upon published or unpublished original work.
2. It must be mailed to the Executive Secretary† of the American College of Physicians on or before August 31, 1930.
3. The thesis or dissertation must be in the English language, in triplicate, in typewritten or printed form, and the work upon which it is based must have been done in whole or in part in the United States or Canada.
4. The recipient of the prize would be expected to read the essay at the next annual meeting of the College, after which he would be officially presented with the prize by the President.
5. The College reserves the right to make no award of the prize if a sufficiently meritorious piece of work has not been received.
6. The announcement of the prize winner will be made not later than two months before the annual meeting.

†Address American College of Physicians, E. R. Loveland, Executive Secretary, 133-135 S. 36th Street, Philadelphia, Pa.

The nurses of the Third District of the Minnesota State Registered Nurses Association have announced the following schedule of fees for private duty nursing in hospitals, effective April 1, 1930: 12 hour duty—$7.00 per day; 10 hour duty—$6.00 per day; 8 hour duty—$5.00 per day.

Dr. Harold D. Palmer, formerly of Saint Paul, graduate of the class of 1927, University of Minnesota, has recently announced his association with Dr. Edward A. Strecker of Philadelphia, in the practice of Neurology and Psychiatry. His offices will be in the new Institute for Mental Hygiene of the Pennsylvania Hospital, Philadelphia.

Beginning this year the American Association for the Study of Goiter will award a cash prize of $300 annually for the best original thesis dealing with some phase of the goiter problem. Theses should be submitted by June 1, to Doctor Walter M. Simpson, Chairman of the Essay Committee, Miami Valley Hospital, Dayton, Ohio. The award will be given immediately following the coming meeting of the Association which is to be held in Seattle, Washington, July 10 to 12, 1930.

STATE ASSOCIATION NEWS

Five Minnesota cities have booked the 1930 medical short courses offered under the auspices of the Minnesota State Medical Association and the University of Minnesota Extension Division. Wadena and Faribault were the last to book them. They opened the series the week of May 12. Willmar, Brainerd, and Winona preceded them.

Meetings took place in Faribault, May 19, and in Wadena, May 23, with executive officers of the association in charge of both. The tuberculosis meeting, arranged by the Minnesota Public Health Association, was held in Faribault, May 26. It is scheduled for Wadena, June 6. Program devoted to cancer, obstetrics, heart disease, arthritis, hospital management and other subjects chosen by the individual county medical societies sponsoring the courses are also scheduled.

F. Manley Brist, investigating attorney for the State Board of Medical Examiners, addressed the Blue Earth Valley Medical Society at Fairmont, May 1, on legal aspects of association affairs.

Officers of the state association addressed a special meeting of the Freeborn County Medical Society at Albert Lea on their way home from the 1930 convention of the Iowa State Medical Association, May 15. S. H. Boyer, president, E. A. Meyerding, executive secretary, and F. Manley Brist, were in the party.

Materials for lay talks on sex hygiene, diphtheria, child health and for a nurses' graduating exercise were sent from state association headquarters to members requesting them this month. This service is available to any member. Address the Minnesota State Medical Association, 11 W. Summit Avenue, St. Paul, Minn.

A PAGE FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

A Public Health Program for the Doctors' Wives

An important and interesting health program evolved by the Women's Auxiliary of the American Medical Association is now before the Public Health Education Committee of the State Association.

This program proposes a very comprehensive lay health education study for county auxiliaries. It is designed, naturally, to cover the entire United States and whatever problem particularly confronts any given community.

The program has already received the approval of the American Medical Association Advisory Council. It is now submitted to the Minnesota Committee by the Auxiliary for approval and criticism and also for selection of what may particularly apply to the general situation in Minnesota.

The Committee has not yet acted upon the program though action is pending. A résumé of the fundamentals upon which the entire proposal is based and the general outline of study follows below for the information of members of the profession in Minnesota in whose communities its effects may be far-reaching.

The fundamentals upon which improvement of public hygiene should be based, according to the proposed program, are, briefly:

1. Recognition of the fact that public health is a highly technical job requiring scientific, technically trained workers.
2. Recognition of the fact that every state, county and city is entitled to a scientific full-time health department.
3. Recognition of the fact that the first and most fundamental job for lay organizations like the Auxiliary is to secure such a department for their city, county or town.
4. Recognition of the fact that where such departments do not exist health activities must be initiated and carried on by volunteer organizations.
5. Recognition of the fact that no health department of whatever kind can do effective work without the intelligent coöperation of the public.

Health officials know, says the national auxiliary, that it is not always the work which makes the greatest emotional appeal to the public which most needs to be done. Unfortunately most women do not know this. It is something that doctors' wives might well undertake to teach other women.

The National Auxiliary recommends, therefore, that each state auxiliary undertake, under the direction and with the help of the Public Health Committee of the State Medical Association, to study the following:

1. Fundamental principles of health promotion and disease prevention.
2. The set-up considered essential by public health experts for an effective state health department, of qualifications of personnel, budget and the like.
3. State health machinery and conditions.

Recommendations for educational work to be done by individual county auxiliaries are to be based upon the conditions found.

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 10:15 o'clock every Wednesday morning over Station WCCO, Minneapolis and St. Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of June will be as follows:

June 4—Cardiac Neurosis.
June 11—Minnesota Department of Health.
June 18—Pyelitis in Young Girls.
June 25—Pituitary Gland.

STATE MEDICAL MEETING

A crowded three days' program is practically complete for what promises to be the most important and valuable state meeting in the history of the Minnesota State Medical Association.

It opens in Duluth, July 15, less than two months from the date of this issue of MINNESOTA MEDICINE, and the program committee wishes to remind members of the association that hotel reservations should be made immediately.

Positive confirmation has been received of the participation of Primarius Lorenz Boehler, Chief Surgeon and Director of the Vienna Accident Hospital, in the symposium on traumatic surgery, which is one of the most keenly anticipated features of the meeting.

Medical men who have been to Vienna recently have been attracted by Boehler's Clinic because of his original ideas in treating fractures. They have all been impressed with the rationality of his treatment and the brilliancy of his results. A great part of his work originated during the World War but he had become quite highly specialized in his work even before the war. In the past nineteen years he has treated more than 10,000 fractures, studied 27,000 roentgenograms, dissected more than 3,000 fractures on the post-mortem table. The latter was done because of dissatisfaction with the end-results with fractures, that he might study the cause of the failures.

Perhaps no other organization in the world is more highly efficient for treatment of fractures than that of Professor Boehler of Vienna.

The distinguished Viennese surgeon will arrive in America early in June. His method of reduction of fresh fractures has caused a sensation in the medical world. It is accomplished painlessly by local anesthesia and in such a manner that the period of treatment is greatly shortened. The Boehler method of treatment will soon be universal, we are told, and the presence of the eminent surgeon should add enormously to the interest in this symposium.

Among other important guests from outside the state who will be present for the meeting are: Karl Meyer, Chicago, Assistant Professor of Surgery at Northwestern University, and Medical Superintendent of Cook County Hospital; Ralph Kinsella, St. Louis, Professor of Internal Medicine at St. Louis University; Arnold S. Jackson, Jackson Clinic, Madison, Wisconsin; E. C. Davidson, Detroit, Junior Surgeon, Harper Hospital, and Attending Surgeon at the Children's Hospital of Michigan; R. S. Dixon, Director of the Division of Social Hygiene, Detroit Department of Health; W. J. Burns, Executive Secretary, Wayne County Medical Society, Detroit; J. G. Crownhart, Secretary, Wisconsin State Medical Association, Madison; Olin West, Secretary of the American Medical Association, Chicago.

Four other important symposia, selected by popular vote of members, are on the program. They will be on Immunology, Malignance, Rheumatic Fever, and Anesthesia.

One evening will be given over to a discussion of the economic trend of medicine; another, to fraternity meetings, and another to the annual banquet of the association.

The Canti film called, "A Cinematograph Demonstration of Living Tissue Cells Growing *in Vitro*," will be shown also as a feature of this year's meeting. It has been secured in response to numerous requests to the committee.

Arrangements for reception of members are practically complete under the direction of the Duluth committee. Attractive entertainment for wives of members has had especial attention.

The complete scientific and entertainment program will be ready for publication in the July issue of MINNESOTA MEDICINE. Watch for it!

SYMPOSIUM ON THE KIDNEY IN HEALTH AND DISEASE

Previous announcement of this unusual opportunity which comes to the very door of Minnesota physicians has already appeared in our columns. While of peculiar interest to internists the subject has a very general appeal.

An effort will be made to correlate many of the known facts under the heading of the anatomy, physiology and pathology of the kidney, with special emphasis on the newly discovered facts regarding the kidney and recent investigative work.

The meeting will open Monday, July 7, 1930, at the University hospital and will continue until Friday, July 18, with an intermission from Saturday noon, July 12, to the following Tuesday to enable attendance at the State Medical meeting in Duluth, which opens July 14. Meetings will begin at 9 A. M. each day and will include morning and afternoon sessions with round table discussions in the evening.

A glance at the following list of well known participants should indicate the treat that is in store for members of the profession:

Dr. A. J. Carlson, University of Chicago.
Dr. G. Carl Huber, University of Michigan.

Dr. E. K. Marshall, Johns Hopkins Medical School.
Dr. R. E. Scammon, University of Minnesota.
Dr. C. M. Jackson, University of Minnesota.
Prof. F. Volhard, Frankfort-on-the-Main.
Dr. A. N. Richards, University of Pennsylvania.
Dr. E. T. Bell, University of Minnesota.
Dr. R. N. Bieter, University of Minnesota.
Dr. H. L. White, Washington University, St. Louis.
Dr. W. F. Longcope, Johns Hopkins Hospital.
Dr. Paul B. Rehberg, University of Copenhagen.
Dr. L. G. Rowntree, Rochester, Minnesota.
Dr. H. Berglund, University of Minnesota.
Dr. A. D. Hirschfelder, University of Minnesota.
Dr. L. Leiter, University of Chicago.
Dr. R. A. Gortner, University of Minnesota.
Dr. Harold Diehl, University of Minnesota.
Dr. McN. Wetherby, University of Minnesota.
Dr. H. P. Wagner, Rochester, Minnesota.
Dr. G. E. Fahr, University of Minnesota.
Dr. N. M. Keith, Rochester, Minnesota.

All correspondence in regard to the symposium should be addressed to the Symposium, University Hospital, Minneapolis, or direct to Dr. Hilding Berglund, University Hospital, Minneapolis.

SCOTT-CARVER COUNTY MEDICAL SOCIETY

Regular meeting of the Scott-Carver County Medical Society was held at New Praque on May 13, 1930. Dr. G. T. Schimelpfenig, of Chaska, was elected to membership in this society. The Honorable Judge C. M. Tifft read a very instructive paper on "Medical Jurisprudence." Dr. E. E. MacGibbon, from the University of Minnesota Dental School, gave a very interesting and instructive address on "Diseases of Mutual Interest to a Doctor and Dentist."

Dr. F. A. Dodge, of LeSueur, one of the charter members of this society, made a few remarks about the beginning of the society. Mr. A. J. Suel, editor from New Prague, gave a short but interesting address on "The Press and the Medical Profession." A rising vote of thanks was given the speakers. It was decided to hold our next meeting, which will be the annual meeting, at Shakopee in June, 1930.

B. H. Simons, M.D., *Secretary.*

MEEKER COUNTY MEDICAL SOCIETY

S. S. Dulude, Dassel, was recently elected president of the Meeker County Medical Society. K. A. Danielson, Litchfield, will be secretary and treasurer; A. W. Robertson, Litchfield, will be delegate; H. E. Wilmot, Litchfield, will be alternate; and D. C. O'Connor, Eden Valley, and A. W. Robertson, Litchfield, will serve as board of censors for the society.

STEARNS-BENTON COUNTY MEDICAL SOCIETY

New officers of the Stearns-Benton County Medical Society are: President, E. M. Kingsbury, Clearwater; Vice-president, H. B. Clark, St. Cloud; Secretary, P. E. Stangl, St. Cloud; Treasurer, F. J. Schatz, St. Cloud; and delegate, C. B. Lewis, St. Cloud.

NORTHWEST PEDIATRIC SOCIETY

Dr. Erling S. Platou of Minneapolis was elected president of the Northwest Pediatric Society at the annual meeting. Dr. E. D. Anderson of Minneapolis is vice president, and Dr. F. G. Hedenstrom of St. Paul, secretary-treasurer.

REDWOOD-BROWN COUNTY MEDICAL SOCIETY

The Redwood-Brown County Medical Society held its annual meeting at New Ulm Union Hospital, May 14, 1930. After a banquet the following were elected to office:

President, Dr. G. F. Reineke, New Ulm; vice-president, Dr. Herman Just, Lafayette; secretary-treasurer, Dr. Wm. A. Meierding, New Ulm (re-elected); delegate to 1931 convention, Dr. Theo. Hammermeister, New Ulm; alternate, Dr. F. H. Dubbe, New Ulm.

Appointment of committees was as follows:

Publicity Committee, Drs. Weiser, Kiefer and Rothenburg. Committee on Public Policy and Legislation, Drs. Rothenburg and Hammermeister. Committee on Maternal and Infant Hygiene, Drs. Weiser and Jamieson.

Mr. F. A. Augustin, of Minneapolis, put on the screen three films showing "Movement of Alimentary tract in Experimental Animals," "The Influence of Drugs on Gastro-intestinal Motility," and "The Anatomy of the Abdominal Wall."

Attorney Linus Glotzbach, of New Ulm, gave a talk on "Medical Economics."

Dr. Herman Just, of Lafayette, read a paper on "Bacillary Dysentery."

A committee was appointed to study and recommend for adoption a basic fee schedule.

Wm. A. Meierding, *Secretary.*

AMERICAN PROCTOLOGIC SOCIETY

The thirty-first annual session of the American Proctologic Society will be held at Buffalo, New York, June 22, 23, 24, 1930, with headquarters at the Statler Hotel.

While the society has a membership limited to fifty Fellows and thirty Associates, regular practitioners who are members of the American Medical Association are cordially invited to attend the meeting.

SOUTHWESTERN MINNESOTA MEDICAL SOCIETY

The fifty-second semi-annual meeting of the Southwestern Minnesota Medical Society was held at the Ashton Memorial Hospital, Pipestone, Minnesota, May 6, 1930.

Drs. N. J. Nessa, S. A. Kellar, and C. W. Forsberg, all of Sioux Falls, South Dakota, gave interesting talks.

The following members were elected to membership in the Society: Dr. D. P. Maitland, Jackson, Minnesota; Dr. B. M. Stevenson, Fulda, Minnesota; Dr. A. L. Pertl, Windom, Minnesota; Dr. S. Engh, Jackson, Minnesota; Dr. V. J. Telford, Edgerton, Minnesota, and Dr. C. V. Bateman, Mountain Lake, Minnesota.

E. G. McKeown, M.D., *Secretary-Treasurer.*

WOMAN'S AUXILIARY
Minnesota State Medical Association

ANNUAL MEETING OF A. M. A. AUXILIARY IN DETROIT—JUNE 23-27

Plans for the annual meeting of the National Auxiliary in Detroit, June 23-27, come on apace. The Auxiliary as an organization is occupied only with business affairs, and has nothing whatever to do with any social gatherings except the official Auxiliary luncheon. Members of the Board of Directors are Mrs. William Gerry Morgan, District of Columbia; Mrs. Olin West, Illinois; Mrs. L. T. Harris, Michigan; Mrs. Walter Jackson Freeman, Pennsylvania, and Mrs. Southgate Leigh, Virginia, chairman. Mrs. Basil Loren Connelly is chairman of the Detroit committee for the convention proper, and Mrs. Burt Shurly of the social activities.

The Roof Garden of the Hotel Tuller, next to the Statler, will be headquarters for all Auxiliary business —registration, meetings, etc.—and the Auxiliary luncheon on Tuesday, June 24. There will be no registration fee, but members will buy their own luncheon tickets—$1.50. The registration bureau will be open Monday, Tuesday and Wednesday, June 23, 24, 25, from 9 to 4; Thursday and Friday, June 26, 27, from 9 to 12. Programs, badges, etc., may all be procured here, and invitations, tickets and transportation cards must all be procured here *in advance.*

The meetings are open to every woman attending the convention, and under Mrs. Hoxie's leadership they are bound to be well worth the trip. There will be three morning sessions, Tuesday, Wednesday and Thursday, June 24, 25, 26. The afternoons and evenings are all left free for sightseeing and social activities, for which many plans are in the making. Details have not yet been announced, but they include motor and boat excursions, and visits to some of the handsome private estates in the environs, including that of Mr. Henry Ford. The Detroit Museum of Art is among the best in the United States. No parties have been scheduled during business hours.

No one may represent her state in any capacity whose state dues are not fully paid. The Chairman of the Committee on Credentials and Registration is Mrs. Ledru Otway Geib, 3860 St. Clair Avenue, Detroit.

Only delegates may take an active part on the floor of the convention, but alternates should attend all sessions and hold themselves in readiness to take their delegates' place if necessary. All resolutions must be in writing and signed, and in the hands of the committee 24 hours before the session at which they are to be presented. Mimeographed copies will be distributed as the delegates take their seats. The Chairman of the Committee on Resolutions is Mrs. Augustus S. Kech, 218 Logan Avenue, Altoona, Pa.

The Board of Directors meets Monday, June 23, at 2:30 P. M. All State presidents and presidents-elect are urged to attend.

The business meeting is scheduled for Tuesday, June 24, at 9:30 A. M., at which committee reports and other matters will be presented.

A Workers' Conference will take place Wednesday, June 25, at 10 A. M. State officers and committee chairmen especially are urged to attend. This meeting should prove interesting to all members of the auxiliary.

A post-convention meeting will be held Thursday, June 26, at 9 A. M., for the purpose of planning the work for the ensuing year.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

MASSEUR SENTENCED TO TEN TO FORTY YEARS IN PRISON

State *vs.* Harold Martin

On Friday, May 16, Harold Martin, 59 years of age, masseur of Minneapolis, was convicted of manslaughter in the first degree following the death of a young woman from an abortion. On May 17th, the Hon. Judge Dickinson sentenced Martin to a term of ten to forty years at hard labor in the State Prison at Stillwater. Martin's sentence to prison was doubled because of his prior conviction in 1914 on a charge of murder in the second degree. Martin served seven years of the previous sentence and was released from prison.

Immediately following his conviction Martin was served with a notice to appear before the State Board of Medical Examiners and show cause why his license to practice massage should not be revoked. The matter was heard by the Medical Board on Tuesday, May 20. There being no appearance on the part of Martin, his license was summarily revoked.

Martin claimed to have been born in Liverpool, England, and to have been a physician and surgeon in that country. However, he never was licensed in this state as a physician and surgeon but in 1927 he secured a massage license from the former Massage Board.

COROZONE

The Corozone unit is a small portable ozonator which can be operated on the ordinary electric light circuit. Ozone in sufficient concentration to kill bacteria is not suitable for ordinary respiration because of its irritant action. Ozone cannot be used as a substitute for good ventilation in a room any more than deodorants or perfume can be used as a substitute for bathing the body. There has been no sound scientific work brought forward to show that there is any place whatever for ozone in problems of ventilation. (Jour. A. M. A., April 3, 1930, p. 1089).

CONSULTATION BUREAU

Wm. A. O'Brien, M.D., *Director*
Minnesota State Medical Association
11 West Summit Avenue
Saint Paul, Minnesota

1. *Question.*—I have a patient, a girl eight years old, who has been sick since April 15, 1930, with fever. During the last week in February, 1930, she had measles with normal convalescence, except that she complained of an earache for about four or five hours one day. Past history: Scarlet fever at three years, complications were cervical adenitis, acute glomerulonephritis with urinary suppression, acute endocarditis of mitral and aortic valves with secondary cardiac hypertrophy and dilation. She was in bed for about six months following scarlet fever and has been underweight and frail since that time. Has bronchitis every winter, especially severe before a tonsillectomy which was done in 1928.

Present illness: On April 15th, her mother thought she had a fever, and on taking it found temperature 102.5. This lasted three or four hours and then went down. It came up the next day a little higher and stayed up a little longer, and continued to do the same up to the present. I saw her first April 21, 1930.

Physical examination revealed old heart lesion; occasional crepitant râle, left lower lobe; palpable spleen. The right ear drum was bulging. Blood vessels along the center were engorged, but there was no tenderness or edema of the mastoid region. There was slight impairment of hearing. Temperature 104.5; pulse 130. I thought from the appearance of the ear drum that it would probably rupture, so I advised waiting a few days. I saw her again April 28th. She still had no complaints other than temperature going up every day. Occasionally had chill before fever and sweating when fever dropped. Temperature would stay up about four hours, and was going to 105.5. I did a von Pirquet, took blood for a Widal, for agglutination against undulant fever—all were ngeative. April 30th, I did a paracentesis. The ear immediately discharged thin watery pus and has been discharging ever since. Discharge is very profuse. Temperature elevation, chills, and sweats have continued as before. Since May 5th, she has been in the hospital. Mastoid area has never been tender or edematous. *X*-ray of chest shows chronic bronchitis; apices are clear. *X*-ray of mastoid shows hazy outline of cells. Leukocyte count varies from 9,000 to 10,000; temperature from 97 to 106.8; pulse 90 to 120. Widal and von Pirquet have been repeated and are negative. Otoscopic examination showed some bulging of posterior wall with pulsation. On one occasion there was a few clumps of pus in the urine, but several specimens since have been negative. There is no tenderness in the kidney region.

What treatment would you follow? Would you advise mastoidectomy or to leave it alone and await further developments?

Answer:—The history and physical findings suggest acute mastoiditis with lateral sinus thrombosis. Mastoidectomy is advised, and if the lateral sinus is involved possible jugular ligation should be done. There is also the possibility of lighting up an old infection of the heart valves and a possible recurrence of the glomerulonephritis. I do not believe it is advisable to wait any longer. An operation should be done at once.

2. *Question.*—Patient is a young man, twenty-four years old, farmer, single, robust in appearance; comes to me complaining of drowsiness and tiredness. He began to notice this along in February of this year. In March felt feverish, but never took his temperature. Has never had any chills. There is a slight headache which gradually grew worse. About three weeks ago had two ulcerated teeth extracted and felt some better for a while, but last ten days has been getting worse and complains of fatigue. Other complaints—nocturia three or four times a night, constipation, poor appetite, fifteen pound weight loss. No particular aches or pains. Father, sixty-one, has been feeling poorly in about the same way and for about the same length of time. Mother living and well. Four brothers and one sister living and well. Under observation his temperature ranges from 99.6 to 104.6, pulse 80 to 108, respirations 20 to 30.

Physical examination showed soft systolic murmur, no glandular enlargement, no areas of tenderness or masses. Today I thought I found a slight enlargement of the spleen. Urine negative except for an occasional granular cast. Hemoglobin 75 per cent, erythrocytes 3,640,000, leukocytes 7,830; differential—polymorphonuclear leukocytes 52, lymphocytes 39, monocytes 9. Blood pressure 94/50. *X*-ray of chest shows calcified lymph nodes, and probably a little more infiltration from hilum out, but this is not definite.

Answer.—The following possibilities should be considered: (1) Undulant fever—please send about 2 to 5 c.c. of blood in a Wassermann test tube to the State Department of Health and mark it "for undulant fever." It is very important to mark the tube. This is a strong possibility because of the number of cases of undulant fever that are present throughout the country. In addition, I would send some blood from the father, who has the same complaint. As a general rule, undulant fever victims feel fairly well, have a high fever, and do not have any special complaints. In addition to testing the blood for undulant fever, the State Department of Health will also make tests for tularemia, typhoid fever, and paratyphoid fever.

(2) Subacute bacterial endocarditis—may be diagnosed by a blood culture and embolic signs in the spleen and kidney. Very often patients suffering with bacterial endocarditis will have a splenic infarct. Hematuria is the other diagnostic sign. Petechia may also be demonstrated in the skin.

(3) Urinary tract infection—pyelitis, pyelocystitis, or perhaps a tuberculosis of the kidney. Examine sediment.

(4) Pulmonary tuberculosis—if there is any sputum, it would be advisable to have it examined for tubercle bacilli.

NEW AND NON-OFFICIAL REMEDIES

The following articles have been accepted by the Council on Pharmacy and Chemistry:

MEAD JOHNSON & Co.

Mead's Dextri-Maltose with Vitamin B.

PARKE, DAVIS & Co.

Ampoules of Pitocin 0.5 c.c.

ELI LILLY & Co.

Merthiolate Jelly, Lilly

Merthiolate Ointment, Lilly

E. R. SQUIBB & SONS

Squibb's Dextrose-Vitavose

FREDERICK STEARNS & Co.

Synephrin

Synephrin Solution "A"

Ampoules Synephrin-Procaine, 3 c.c.

Hypodermic Tablets Synephrin-Procaine

The following article has been exempted and included with the List of Exempted Medicinal Articles (New and Non-official Remedies, 1929, p. 481):

G. D. SEARLE & Co.

Stable Solution Dextrose and Sodium Chloride (Searle)

TRUTH ABOUT MEDICINES

Diphtheria Toxin-Antitoxin Mixture 0.1 L. + Nonsensitizing (Sheep).—A diphtheria toxin-antitoxin mixture (New and Non-official Remedies, 1929, p. 360), each c.c. of which constitutes a single dose of diphtheria toxin neutralized with the proper amount of antitoxin produced from sheep. It is marketed in packages of three vials, each containing 1 c.c.; in packages of one vial containing 10 c.c.; in packages of one vial containing 30 c.c.; and in packages of thirty vials, each containing 1 c.c. United States Standard Products Co., Woodworth, Wis.

Tablets Tutocain No. 6.—Each tablet contains tutocain (New and Non-official Remedies, 1929, p. 51) 0.05 Gm. Winthrop Chemical Co., Inc., New York.

Ampoules of Pitocin 0.5 c.c.—Each ampule contains more than 0.5 c.c. of pitocin solution (Jour. A. M. A., July 13, 1929, p. 117). Parke, Davis & Co., Detroit.

Merthiolate Jelly 1:2,000.—It contains merthiolate (Jour. A. M. A., December 7, 1929, p. 1809) 0.05 per cent, eucalyptol 0.016 per cent, eugenol 0.016 per cent in a water-soluble base. Eli Lilly & Co., Indianapolis.

Merthiolate Ointment 1:1,000.—It contains merthiolate (Jour. A. M. A., December 7, 1929, p. 1809) 0.1 per cent in a petrolatum base. Eli Lilly & Co., Indianapolis. (Jour. A. M. A., April 19, 1930, p. 1237.)

Butesin Picrate Eye Ointment.—An ointment containing 1 per cent of butesin picrate (New and Non-official Remedies, 1929, p. 54) in a petrolatum base. Abbott Laboratories, North Chicago.

Pneumococcus Antibody Solution, Types I, II and III Combined-Mulford (New and Non-official Remedies, 1929, p. 346).—This product is also marketed in packages of four 50 c.c. double-ended vials with one complete intravenous outfit. H. K. Mulford Co., Philadelphia.

Ampules Dextrose (d-Glucose) 10 Gm., 20 c.c.—Each ampule contains dextrose (New and Non-official Remedies, 1929, p. 240) 10 Gm., in distilled water, to make 20 c.c. Lakeside Laboratories, Inc., Milwaukee, Wis.

Ampules Sodium Cacodylate 0.243 Gm. (3 3/4 grains), 5 c.c.—Each ampule contains sodium cacodylate (New and Non-official Remedies, 1929, p. 73) 0.243 Gm. (3¾ grains) in 5 c.c. of solution. Lakeside Laboratories, Inc., Milwaukee, Wis. (Jour. A. M. A., March 1, 1930, p. 634.)

Squibb's Dextro-Vivatose.—A mixture of Squibb's vitavose (New and Non-official Remedies, 1929, p. 244), 1 part, and dextrose, 2 parts. E. R. Squibb & Sons, New York. (Jour. A. M. A., March 29, 1930, p. 920.)

FOODS

The following products have been accepted as conforming to the rules of the Committee on Foods of the Council on Pharmacy and Chemistry of the American Medical Association:

Klim Powdered Whole Milk (Merrell-Soule Co.).—It is whole milk from which all but about 2 per cent or less of the normal water has been removed by means of the spraying process of drying milk. It contains: fat, 28.0 per cent; protein, 26.7 per cent; lactose, 38.0 per cent; ash, 5.8 per cent; water, 1.5 per cent. Klim milk is used for supplementary feeding to be used according to a physician's formula.

Borden's Natural Flavor Malted Milk (The Borden Co., New York).—It is a processed mixture of barley malt, wheat flour and whole milk, reduced to powdered form. The product contains: fat, 9.2 per cent; protein, 15.5 per cent; lactose, 13.5 per cent; maltose, 35.6 per cent; dextrin, 20.2 per cent; ash, 3.8 per cent; moisture, 2.2 per cent. It is easily digested.

Mellins' Food (Mellin's Food Co., Boston).—It is a milk modifier. It contains: fat, 0.16; protein, 10.35; maltose, 58.88; dextrins, 20.69; soluble carbohydrates, 79.57; salts, 4.30; water, 5.62. Mellin's Food is a soluble, easily digestible dry extract made from wheat flour, wheat bran, malted barley and potassium bicarbonate.

Mellin's Food Biscuits (Mellin's Food Co., Boston).—They contain a large percentage of Mellin's Food. (Jour. A. M. A., April 12, 1930, p. 1145.)

Peter Pan Bread (P. F. Peterson Baking Co., Omaha).—A thoroughly baked, white bread having a soft velvety texture and sweet flavor.

Clapp's Original Approved Baby Soup and Strained Vegetables (Harold H. Clapp, Inc., Rochester, N. Y.).—Baby Soup: A combination of beef juice and vegetables. Wheatheart Soup: A combination of wheat germ, vegetables and cereals. Strained Vegetables: Spinach, wax beans, carrots, asparagus, peas, beets, prune pulp, apricot pulp and tomatoes. In these products all possible food values are retained and the least amount of water is used in cooking.

Checkr-Redi-Cooked Oats or Checkr Rolled Oats (Ralston Purina Co., St. Louis).—Checkr-Redi Cooked Oats have been precooked to bring out their mellow

flavor and to make them quickly prepared and easily digested.

Minute Gelatin (Minute Tapioca Co., Inc., Orange, Mass.).—Pure granulated gelatin offered in convenient size cartons for household use. (Jour. A. M. A., March 1, 1930, p. 635.)

Borden's Sweet Chocolate Flavor Malted Milk (The Borden Co., New York).—It has the following average composition: fat 6.7%; protein 9.7%; sucrose 47.8%; other carbohydrates (maltose, dextrin, lactose) 31.0%; ash 2.4%; insoluble chocolate solids 0.4%; moisture 2.0%. This product differs from other chocolate malted milks in that the cocoa is cooked.

Quaker Puffed Wheat (The Quaker Oats Co., Chicago).—It is made from whole wheat; 25 per cent is bran. The minerals are retained. Puffed Wheat with whole milk is approximate in energy value to a dish of hot cooked cereal.

Quaker Oats (The Quaker Oats Co., Chicago).—Brands: Quick Quaker Oats; Rolled Quaker Oats; Mother's Oats; Quick Mother's Oats. Quaker Oats provides 50 per cent more protein than wheat, 60 per cent more than wheat flour, more than twice as much as rice; 100 per cent more than cornmeal. It is rich in minerals and Vitamin B.

Instant Postum (Vacuum Cereal Beverage) (Postum Co., Inc., Battle Creek, Mich.).—A beverage made only of whole wheat and bran roasted with a small portion of sugar-cane molasses. It contains no caffeine.

Postum Cereal (Postum Co., Inc., Battle Creek, Mich.).—It is made only of whole wheat and bran roasted with a small portion of sugar-cane molasses. It contains no caffeine.

Sac-a-Rin Brand of Canned Vegetables (Kings County Packing Co., Oakland, Calif.).—Brands: California Tomatoes; California Asparagus; California Spinach. These are vegetables packed without added salt or sugar for dietetic purposes. For use when an intake of carbohydrate—particularly sugar—is to be restricted.

Sanka Coffee (Sanka Coffee Corporation, Brooklyn and Los Angeles).—A blend of South American coffee with Mocha and Java. The caffeine is removed by a process which removes 97 per cent or more of the caffeine originally present in the bean (based on 1.1 per cent of caffeine). It may be used when other coffee has been forbidden.

Milk Packed Coconut (Franklin Baker) (Franklin Baker Co., Hoboken, N. J.).—The shredded coconut is packed in cans without the addition of sugar, the can being filled with coconut milk.

Franklin Baker Premium Coconut (Franklin Baker Co., Hoboken, N. J.).—The shredded coconut is mixed with added sugar and 5 per cent glycerin and passed through driers.

Southern Style Coconut (Franklin Baker) (Franklin Baker Co., Hoboken, N. J.).—Coconut meat is passed through an automatic shredding machine, after which the added sugar is mixed with the coconut meat, the resultant product being passed through driers. The product is packed in cans in an atmosphere of carbon dioxide.

Hellman's Mayonnaise (Richard Hellman, Inc., Long Island City, N. Y.).—It is made from a blend of edible vegetable oils, vinegar, egg yolk, spices and condiments beaten to a stable emulsion.

Minute Tapioca (Minute Tapioca Co., Inc., Orange, Mass.).—It is made from tapioca flour. The flour is bolted, mixed with water, steam cooked, granulated and dried.

Association of Hawaiian Pineapple Canners.—On the basis of an average of representative samples of Hawaiian pineapples there is obtained a value of 88 calories per hundred grams of canned pineapple. There are better sources of a single vitamin, but as an all around source of vitamins the pineapple takes unusually high rank. Canned pineapple is an article of diet of substantial food value. (Jour. A. M. A., March 8, 1930, p. 716.)

THE PELLAGRA PREVENTIVE ACTION OF CANNED SALMON

In connection with studies relating to the pellagra preventive properties of various food substances the United States Public Health Service has recently announced that canned salmon (Alaska chum) contains the pellagra preventive factor. By reason of its potency in preventing pellagra and its availability in the preserved state, salmon may be considered a fair substitute for meat in the area of pellagra endemicity where meat is not readily available. The demonstration of the pellagra preventive value of canned salmon furnished further evidence of the soundness of the working hypothesis that black tongue in dogs is the analogue of pellagra in man.

CITRIN NOT ACCEPTABLE FOR N. N. R.

The Council on Pharmacy and Chemistry reports that Citrin is marketed by the Table Rock Laboratories in the form of capsules claimed to contain "50 mgm. cucurbocitrin," the latter being "a non-toxic glucosid-saponin processed from the seed of the watermelon (Cucurbita Citrullus)." In the information submitted to the Council, Citrin is stated to be "the crude extract" obtained from the watermelon seed. The available evidence does not indicate that the product is a pure glucoside. Citrin is stated to be "for the treatment of hypotensive cardio-vascular disease" and is advertised as "The new therapy for vascular hypertension." The Council reviews the available evidence for the usefulness of Citrin and explains that the question at issue seems to be whether the observed lowering of blood pressure by drugs is of any great clinical value, and, when this does occur, to what extent it is due to the drug and to what extent to other factors. Altogether, the Council concludes that the clinical evidence does not establish the therapeutic usefulness of Citrin; hence, the Council declared Citrin unacceptable for New and Non-official Remedies. (Jour. A. M. A., April 5, 1930, p. 1067.)

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of April 9, 1930

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, April 9, 1930. Dinner was served at 7 p. m. and the meeting was called to order at 8 p. m. by the President, Dr. Emil S. Geist. There were 52 members present.

Minutes of the March meeting were read and approved; also the minutes of the Executive Committee meeting of March 26th.

Dr. C. D. Freeman read the following memorial to Dr. Paul B. Cook:

Dr. Paul B. Cook, a member of this Academy since 1911, died February 9, 1930, at Miami Beach, Florida, where he had gone to recuperate his health.

He had practiced in St. Paul since his graduation from the University of Minnesota in 1900. He was born in Rochester, Minnesota, the son of George Clinton and Elizabeth Burns Cook. He made his home with his sister, Mrs. F. B. Kellogg, in St. Paul, not having been married.

Dr. Cook was a member of Ramsey County Medical Society, Minnesota Academy of Medicine, Twin City Urological Society, Minnesota Dermatological Society, and the American Urological Association.

Until 1907 he practiced general medicine, when he went to Vienna for a year and did postgraduate work in dermatology and urology, to which specialties he limited his work until his death.

He enlisted early in the last war and after spending several months at Camp Riley and Camp Jackson he was sent to France with the rank of Major in the Medical Corps, where he remained until after the Armistice.

During the last few years of his life Dr. Cook traveled very extensively. He visited South America, Hawaii, took a world cruise, and last year took an extended tour around Africa. Shortly before his last illness he was planning another trip and stated that his only trouble was to find a new place to go.

Dr. Cook is survived by two sisters, Mrs. F. B. Kellogg and Mrs. F. J. Ottis of St. Paul, and a brother, George Cook of Rochester, Minnesota.

Dr. Cook's fine qualities won for him the affection and loyalty of those who knew him well. He was well known by all medical men in this vicinity. As a tribute to him it may be said with no fear of contradiction that he possessed two qualities necessary to every physician: he was honest, he was ethical.

The Committee: S. E. Sweitzer,
F. E. B. Foley,
C. D. Freeman, Chairman.

Dr. A. S. Hamilton read the following memorial to Dr. C. Eugene Riggs:

Dr. C. Eugene Riggs, physician and scholar, educator and original investigator, was born in West Unity, Ohio, in 1853, and died in St. Paul, April 3, 1930. He was descended from an old Maryland family and was attracted to St. Paul, as many other physicians before him, partly by the hope that the vaunted Minnesota climate might heal a suspected pulmonary weakness.

His early education was obtained in the public schools of Ohio, and he later attended Ohio Wesleyan University, where he received the degree of A.B. in 1877, and that of M.A. in 1880. At one time in that period of his life he expected to enter the ministry. He later turned to medicine and his first training was received in the office of his brother, Dr. J. U. Riggs, of Bryan, Ohio. He subsequently had one year in the Medical College at Nashville, Tenn., and was graduated in 1880 at the College of Physicians and Surgeons in Baltimore, Md. After one year as intern at the Women's Hospital, in Baltimore, he came to St. Paul in the spring of 1881 and engaged in the general practice of medicine. Apparently, at this time he had no special interest in diseases of the nervous system and, when, almost immediately on his arrival, he was asked to present a course of lectures on Materia Medica in the St. Paul Medical College, he accepted. Later he was offered the chair of Nervous and Mental Diseases in the same institution, which offer he also accepted, becoming thus the pioneer in Minnesota in the private practice of neurology and psychiatry. When the medical department of the University of Minnesota was established, he was made Professor of Nervous and Mental Diseases and in 1908 became Director of the Department as well as professor. Preparatory to the reorganization, January 15, 1913, he resigned and in June of that year was made Emeritus Professor of Nervous and Mental Diseases, which position he held until his death. Dr. Riggs was an excellent teacher and an inspiring spirit in all his associations with his students and fellow practitioners and to his patients he imparted confidence and courage. He had an unusual knowledge of current literature in his own field and almost to the last day of his life he read his journals, clipped from them the articles which seemed to him especially valuable and put them away in his filing system. Notwithstanding this familiarity with neurologic and psychiatric literature, he once told me that during his years of active teaching he never delivered a lecture to the students without spending the evening preceding in review of the subject matter. But his interests were not limited entirely to clinical fields and on his return from a trip abroad he brought back the equipment for a neuropathological laboratory, the first private neuropathological laboratory in the state; and in this laboratory Dr. L. B. Wilson worked out the histology of Dr. Riggs' case of subacute combined degeneration with pernicious anemia—the first reported in the state and the third reported in this country.

Throughout a long and active career in the practice of medicine, covering forty-nine years, he was a leader in all movements having to do with his specialty. For ten years preceding the establishment of the State Board of Control, Dr. Riggs was Chairman of the State Lunacy Commission. On one of his trips abroad, he was authorized by Governor Merriam to investigate

the insane hospitals of Europe for the purpose of reproducing in Minnesota whatever was of value in European methods of care for the insane. He also interested himself actively in the matter of providing detention wards in our larger cities, in the need of special care for the criminal insane and in the imperative necessity for a voluntary commitment law.

Dr. Riggs was a member of the American Neurological Association, the American Psychiatric Association, the American Medical Association, the Ramsey County Medical Society and the Central Neuropsychiatric Association. He was one of the founders of the Minnesota Academy of Medicine and a past-president of the Academy, and a founder and first president of the Minnesota Neurological Society. He was at one time chairman of the section of Nervous and Mental Diseases of the A. M. A., and was president at one time of the Minnesota State Medical Society.

He was also a member of the Society of Colonial Wars and of the Sons of the Revolution, of which he had been president, and of the Minnesota Club.

Dr. Riggs was a member of the Plymouth Congregational Church of Minneapolis, Past Master of Summit Lodge, a member of Osman Temple and Paladin Commandery, as well as a 32nd Degree Mason.

Dr. Riggs was a very religious man, as one incident of his early career shows. Though he had been offered a position as Chief of the Department of Neurology and Psychiatry in the St. Paul Medical College, the school ceased to exist before he could give his first course of lectures and was merged with the Minneapolis College Hospital in Minneapolis. The meeting for the final settlement of the details of the union and the allocation of titles was held on a Sunday afternoon and Dr. Riggs announced that rather than attend the meeting on Sunday he would renounce his claim for a position on the faculty and he kept his word, but, nevertheless, was given the professorship in his specialty.

Despite his large private practice and his duties as a teacher, Dr. Riggs found time to be a good citizen and to contribute to medical literature some 80 or 90 papers dealing largely with the various phases of neurology and psychiatry. The first article of which I can find any record was published in the Southern Clinic of Richmond, Va., in 1881, under the title "Atresia of the Female Genital Tract," obviously at a time when he had no thought of his ultimate relation to psychiatry. The last article I have found is entitled "Address of Greeting to the American Psychiatric Association" at Minneapolis, June, 1928, published in the American Journal of Psychiatry 1928-1929.

In the intervening period of forty-nine years Dr. Riggs discussed a very wide range of neurologic and psychiatric topics, and though it is hardly proper to detail them here, I may refer specially to two historical articles which are of distinct value in understanding the early medical situation in Minnesota. "Minnesota Medicine in the Making" was published in the State Journal in October, 1921, and the "Reminiscences of a Neurologist" in the same journal of January, 1928.

Perhaps the high point of Dr. Riggs' professional career was reached the night of April 26, 1928, when he was the guest of honor at a dinner tendered him at the Minnesota Club by a group of professional friends.

Of Dr. Riggs' personal character it is less easy to write. To the public, he was the gentleman and the aristocrat. Severe in his principles, he lived his life according to his creed, never deviating from it. He was not one with whom it was easy to make friends, but his friendship, once given, was loyally maintained. One who knew him well has assured me that he never once heard Dr. Riggs utter a profane word, hardly even a slang phrase. As a past-master in the handling of patients, he was well known, but of his kindness, his consideration and his charity to patients, his immediate associates alone were cognizant.

His home life was ideal. On September 11, 1884, he married Mabel Elizabeth Pratt at Bryan, Ohio, and in his wife, to a very unusual degree, he found a companion who shared his ideals, helped him in his labors and enabled him to devote all his energies to the attainment of the very best in his professional life. To the limited friends who were privileged to enjoy it, the hospitality of this household is a happy memory not easily forgotten.

The Committee: W. A. Jones,
E. M. Hammes,
A. S. Hamilton, Chairman.

The scientific program of the evening consisted of two theses.

Dr. E. V. Goltz (St. Paul) read his thesis entitled "Primary Carcinoma of the Lungs and Bronchi."

DISCUSSION

Dr. C. E. Connor (St. Paul): I think that none of us sees enough of this type of case to have a very wide experience; I am sure I haven't. Carcinoma of the lung can modify the normal bronchoscopic picture in either one of two ways: 1. By bronchial pressure with intact mucosa, in which case the bronchoscope is apt to show a stenosis or, if extreme, a complete occlusion. The latter would be rather unusual. 2. By the appearance in the air-way of the tumor itself. These tumors may assume either one of two different types, the fungating, flat, bleeding tumors which suggest malignancy and whose origin is at times determined with difficulty, or the pedunculated papillomatous structure which does not at first suggest carcinoma. The latter, however, is not the type which would give the characteristic clinical picture that Dr. Goltz has described. If the tumor has invaded the air-way, the condition of the bronchial tree will depend a good deal on the size of the tumor. If the tumor is small there will be very little change other than the collection of sanguineous fluid. If the tumor has reached a stage where occlusion is marked, either atelectasis or bronchiectasis may be found.

The bronchoscope does offer a distinct aid in diagnosis and every suspicious case should be bronchoscoped. The results are sometimes surprising. Biopsy

is also important. In the case of the pedunculated papillomatous tumor that is occasionally reported, permanent cure may be obtained, lasting over 5 years. Therapy in the commoner clinical type with various lung changes consists primarily of measures for temporary relief, usually aspiration, which will give the patient considerable relief. Another measure, but one which I have never used, is the implantation of seeds. Deep therapy may be tried, but usually avails little.

Dr. Thomas S. Roberts (Minneapolis): Being called upon, I will speak but I cannot add anything material to this discussion since in some 40 years of practice I have seen only a few cases of carcinoma of the lung and they were not primary in the lung. During a year spent as intern in one of the largest hospitals in Philadelphia there never was a case of primary carcinoma of the lung in the very large number of autopsies that were done there, so far as I can recall. A very considerable number of these were presided over by Dr. William Osler, who never failed to discover and correctly interpret whatever was present.

A case of carcinoma of the lung, though not primary in the lung, seen recently, may be of interest in some of its aspects. A man 66 years of age seemed to be in the best of health until he became greatly depressed mentally (for reasons that were quite sufficient it seemed), when there began a physical decline which was attributed to the state of mind rather than to any disease. He was examined by several physicians, who found nothing definite. After a few weeks there developed a condition which Dr. Sam Sweitzer agreed was probably pellagra of a secondary type. The patient had been eating irregularly and insufficiently, substituting for food a certain amount of alcohol and worrying incessantly, which suggested the possibility of pellagra as an explanation of the unusual skin lesions that appeared on feet, hands and head. Later he developed a moderate cough, some difficulty in swallowing, lost flesh markedly, and still his condition was considered to be largely mental. About this time we went to Rochester and he went through the Clinic, was *x*-rayed, etc., and nothing very definite was discovered, and he came away with the opinion that if he would take a little different view of things he would probably be all right. He did actually gain in weight and made one or two trips to Chicago on business, which looked as though there was not very much the matter with him. Then he began having some pain and distress in the chest and epigastrium. We dined together several times and it was noticed that at the beginning of a meal he seemed to have a little hesitancy in swallowing, with some cough, but then went on and ate his meal without apparent difficulty. As time went on he began to slip back again, had more distress generally, became partially bedridden, and had one or two attacks of sharp pain in the *left* chest. The physical signs were still indefinite. Again we went to Rochester, but before going had a complete set of *x*-rays made here of the chest and abdomen; these showed nothing in the chest but there was apparently some enlargement of the spleen. Another set of pictures was made at the Mayo Clinic and for the first time there was a slight shadow in the *right* lung. There was some difference of opinion as to what this indicated—between an interlobar empyema and a malignant growth. (It is only fair to say that a proposal to make a bronchoscopic examination was declined as the patient's condition at this time was such as to make it seem hardly worth while. It would no doubt have cleared up the uncertainty.) From this time on he was confined to bed mostly, developed a severe cough with offensive sputum, failed rapidly, and died without a positive diagnosis. Dr. E. T. Bell performed an autopsy and found an extensive carcinomatous involvement of the right bronchus, a large abscess in the upper lobe of the right lung, and the esophagus surrounded and partly destroyed by a carcinomatous mass where it came in contact with the involved bronchus. At this point it was densely thickened and indurated, and denuded of the mucous membrane. Through this extensively diseased esophagus, stomach tubes had been passed several times without causing any noticeable distress to the patient, strange as it may seem. It was Dr. Bell's opinion that the carcinoma was primary in the esophagus and secondary in the lung. Other autopsy findings were an enormously enlarged spleen, weighing 1,000 grams, the lower half being the seat of a large metastatic carcinoma measuring 10×12 cm., the central portion necrotic; an open ulcer, 1.2 cm. in diameter, immediately on the gastric side of the pyloric ring; numerous diverticula of the sigmoid, one at least showing acute inflammation; and a moderate grade of cholecystitis with a single small gallstone—certainly a formidable pathological array, and yet this man had comparatively little physical disability until the last few weeks of his life. It was not such a great while before his death that he went to Chicago alone and took care of considerable important business. He must have had this devastating growth developing during the time that we were accusing him of being simply despondent and downhearted. Toward the last, when the mental depression waned almost entirely, about his only complaint was a distress in the region of the stomach and lower chest and he was wont to say, "If I could only get rid of this discomfort I would feel all right."

Dr. C. B. Wright (Minneapolis): How long was the duration of the condition in this man?

Dr. Roberts: I can't say exactly, the onset was so indefinite. He was apparently well until one day something happened to disturb his business relations that depressed him greatly. He went to his summer home in northern Minnesota and sat on the porch most of the time brooding. Early that fall he showed signs of failing, but was not considered seriously sick. He died the following July. Not one of the *x*-rays showed anything suggestive until the last set, about 8 weeks before his death. I imagine he may have had some difficulty in swallowing and perhaps some discomfort that first summer, but he was not a man to complain.

It all goes to show how mortally stricken a man may be and yet how difficult it may be sometimes to find out what is the matter.

Dr. E. K. Geer (St. Paul): I have seen five of these

primary lung carcinomas in the last ten years. The last one is interesting enough to report briefly. A man in his late forties was admitted to Pokegama Sanatorium a year ago with an old bilateral upper lobe tuberculosis. In 1914 he had had an active tuberculosis with positive sputum, and the loss of weight, cough and so forth of which he complained before coming to the sanatorium in 1929 was thought to be a recurrence of his old lung lesion. On the usual sanatorium régime he gained 40 pounds but did not lose his cough. His *x*-ray films on admission showed the old upper lobe tuberculosis and also a shadow at the right root which could have been interpreted as a large gland. About two months ago he complained of dyspnea and on examination an atelectasis of his right lower lobe was found with marked displacement of his heart and mediastinum to the right. Bronchoscopy done by Dr. Greth Gardiner revealed an intrabronchial growth in the right lower bronchus and a section of this growth showed it to be cancer. The lack of characteristic cough, the absence of chest pain, and the suddenness with which it expressed itself clinically were certainly atypical. The other cases I have seen conformed very well to the chief points brought out so clearly by Dr. Goltz.

Inasmuch as physical examination is often disappointing and the *x*-rays films apt to be misleading because so many are reported as "probably inflammatory," it seems to me that from the diagnostic side we will spot this form of cancer much more frequently if we resort to bronchoscopy more often in obscure lesions.

The treatment of primary cancers of the lung has been hopeless in my experience. Deep *x*-ray therapy may prolong life a little but it certainly does not cure.

Dr. Herbert Davis (St. Paul): In how many of those cases did you find tuberculosis?

Dr. Geer: The case I have just mentioned was the only one in which clinically demonstrable tuberculosis in the lung was associated with primary lung cancer.

Dr. S. Marx White (Minneapolis): I wish to call attention to certain sources of error in diagnosis common when carcinoma is developing in the lung. I have been in a position to see a fair number of cases during many years' service at the University Hospital in our work in the Clinic. A case occurring in a well-known internist in Cleveland about two years ago illustrates one of the sources of difficulty. This physician, whose name would be familiar to everyone here, had, with an insidious onset, a suppurative process in the left interlobar fissure. This process required drainage but, because it covered up the primary process, the diagnosis of carcinoma could not be made at first but subsequent developments made that diagnosis clear. I have seen such suppurative interlobar processes in carcinoma and they are a serious element of confusion.

A more common cause for difficulty in diagnosis is in the differentiation from pulmonary tuberculosis, particularly when the carcinoma develops in an upper lobe; the *x*-ray shadow may be that of a pyramid of greater density than normal, the apex toward the hilus of the lung. With the tendency on the part of the roentgenologist to report such shadows as tuberculosis, even in the absence of such phenomena as cavitation or other processes which are highly significant of a destructive process like tuberculosis, the roentgen diagnosis is given greater value than it deserves and the clinician is likely to accept the diagnosis as final when it should be taken only as a part of the whole picture.

A third difficulty lies in the fact that with carcinoma of the lower lobe pleural effusion very frequently occurs. The effusion masks the infiltrative processes in the lung and there is nothing in the *x*-ray picture, therefore, to suggest an intrapulmonary process. The frequent occurrence of blood in such effusions is suggestive and often helpful in calling to mind the possibility of carcinoma. The fact that pain is also usually a predominant symptom in carcinoma adds another suggestive point.

Dr. Goltz's paper is a very helpful contribution to a subject of great importance and it is clear that carcinoma of the lung, while it has certain features highly suggestive from the clinical standpoint, is liable to simulate a number of conditions, and unless we think of it as a possibility in all cases, especially with people in the cancer age, we can easily miss the diagnosis.

Dr. C. N. Spratt (Minneapolis): In an abstract of an article on tobacco and tobacco-smoke as a factor in cancer, in the Journal of the A. M. A. for March 29, 1930, Lickint reviews over 4,000 cases of cancer of the bronchi and lungs from the literature. He finds this five times more common in men than in women. He believes "that this is to be explained in part by the great increase in cigaret smoking, with its attendant inhalation. Not only smokers but non-smokers are exposed to this danger in smoke-filled rooms. Because of the finer state of division of the particles in tobacco smoke, they have a much greater penetrating power than have particles of dust. In the case of tobacco smoke, the maximum amount of irritation is produced because, in addition to the mechanical irritation (particles of carbon), there is also a chemical (tarlike combustible products) and a thermal (current of heated air) irritation."

According to Dr. Henry W. Cook, in an address delivered at a convention of life insurance presidents in December, 1929, the expectance of life has not increased except in the first two years, and no appreciable gain is shown after the age of 50, "and a very marked loss is shown in several very important diseases such as heart disease—now the largest single mortality factor—in cancer, in diabetes, and in death from automobile accidents. In other words, while a baby born today has an increase in life expectancy of 17 years, an adult of 50 or over has no increased expectancy in comparison with 50 years ago, and probably even in comparison with 2,500 years ago, in the days of Pericles."

Dr. Bloodgood has called attention to the fact that cancer of the lip is more common in men than in women, and has brought up the question of its increased frequency in the latter as smoking becomes more common among them.

Dr. A. R. Hall (St. Paul): One of the interesting things brought out by the essayist is the increase of carcinoma of the lung. The essayist states that this is a real increase as is shown by autopsy statistics. Au-

topsies are probably not much better done today than they were 25 years ago; what I mean is that carcinoma of the lung would not have been much more likely to have been missed in an autopsy 25 years ago than it is today, and yet statistics from different countries of the world show that, whereas the primary seat of all carcinomas 25 years ago was found to be in the lung in about 1 or 2 per cent of cases, today in all carcinomas the primary seat is found in the lung in about two to three times this percentage. The statistics from the different hospitals in different countries are fairly uniform in this increase. It is interesting to speculate as to what the cause of this increase may be. It must be some world-wide cause. As Dr. Goltz has stated, many different things have been considered that might be a causative factor. The one lung irritant which has been suggested and which would seem to fill the requirement of being world-wide is influenza.

As to diagnosis, the most important thing is that we do not forget that there is such a thing as carcinoma of the lung. It seems to me that pain is more often present in carcinoma of the lung than it is in other obscure lung conditions.

In the way of treatment, deep *x*-ray therapy, while it does not cure, does seem to slow up the process.

Dr. L. C. Bacon (St. Paul): My excuse for prolonging the discussion is that this thesis is a timely and valuable one and is entitled to free discussion. The matter of treatment has not been touched upon. At the present time deep roentgen ray therapy is the only method of treatment which gives promise of possible benefit and even with this we are not hopeful. I have come in contact with two casces of lung carcinoma and the result in one of them indicates that deep therapy should be resorted to vigorously.

The first was a woman of 58 years, slender and small, with a carcinoma of the right breast which was removed by radical operation. She returned in a few months with a metastasis involving the right lung, lower and middle lobes. Deep roentgen ray treatment was vigorous and after a stormy period of about three months, during which she expectorated quantities of pus and fibrous tissue, she regained a fair degree of health and lived three years, finally dying from an influenza. Autopsy disclosed complete destruction of the right lung with collapsed thorax completely filled by the remaining thoracic structures. No carcinomatous tissue could be found.

The second case, a large stout woman, 62 years of age, had been in the University Hospital with a diagnosis of carcinoma of the right lung. She had been treated with *x*-ray until she had refused further treatment and returned home. I came into the case only a few days before her death. Autopsy disclosed complete destruction of the right lung and metastases in the liver and left kidney confirmed the diagnosis. Pleuritic fluid was present and the chest wall had not collapsed. She gave a history of repeated drainage of the pleuritic fluid and I drained it once during my charge. She apparently died from exhaustion.

One case living in comfort for three years should admonish us to give these very hopeless cases the possible benefit of *x*-ray.

Dr. Goltz (in closing): I have nothing more to add, but wish to thank the members for the discussion of my paper. I think the important thing to gather from this paper and from the discussions is that one should bear this condition in mind in all obscure chest conditions.

Dr. Emil C. Robitshek (Minneapolis) read his thesis entitled "Acute Perforated Peptic Ulcer."

DISCUSSION

Dr. E. M. Jones (St. Paul): The hour is late but I have some interesting plates I wish to show. The patient, a young man 21 years of age, was admitted to the Ancker Hospital at 8:30 a. m. March 22, 1930. He states that the night before admission he became nauseated and vomited. He retired but was awakened at 4 a. m. by a violent pain in his upper abdomen. He took some soda and the pain became worse. A doctor was called and he was sent to the hospital. On admission he was seen by Dr. Colvin. The man was having severe pain in the upper abdomen. The abdomen was rigid but not the so-called board-like abdomen. Temperature 98°, pulse 80, leukocytes 10,000. The most probable diagnosis was cholecystic disease or perforated ulcer. An hour after admission the picture had entirely changed. He was having no pain and only a slight muscular rigidity in the upper right quadrant of the abdomen. It was decided to treat him expectantly. An *x*-ray plate of the abdomen was ordered and it showed air between the liver and diaphragm. I saw the man again in the afternoon and his condition was the same, with the exception of a temperature rise to 101°. In view of the *x*-ray findings, there was no question as to the diagnosis of a perforated viscus. Five per cent of perforated ulcers are sealed locally and do not develop general abdominal symptoms. Another picture was taken and the air bubble was again demonstrated above the liver. In spite of the patient's good condition, but because of the *x*-ray findings I finally advised operation, but the patient would not consent. Later in the evening he was again seen and his condition was so satisfactory that I decided to continue the expectant treatment.

Cases of perforated ulcer often show apparent improvement after a few hours but then the symptoms of general peritonitis begin to develop and this of course is the reason for early operation. This patient, however, was continually improving and nothing developed pointing to a general peritoneal involvement and we felt these symptoms would have developed by evening as it was 14 hours after the onset.

On the seventh day a picture was taken showing that the air had disappeared, and on the ninth day some barium was given and a duodenal ulcer was demonstrated. I am not advocating the non-surgical treatment of these cases but I do not believe any one watching this man would have operated upon him before we had these *x*-ray pictures.

I think a case like this impresses us with the fact that we must carefully evaluate our clinical symptoms.

Dr. Alex R. Colvin (St. Paul): First of all I would

like to congratulate the essayist on his paper. It is very valuable because of the comprehensive and yet concise statement of the views of those who have large experience in the subject just presented by Dr. Robitshek.

Regarding the case reported by Dr. Jones, I saw this man when he first entered the hospital and the question then seemed not "has he a perforated ulcer?" but "has he a perforating one?" The patient said he had had very severe pain, but at the time of examination he had very little. He had some rigidity but not a board-like rigidity. Whether or not he should have been operated on may be a debatable question. I do not think it would have been a mistake to operate. Certainly the free air above the liver seemed a positive indication, but then clinically he was getting well.

Regarding the number of times an ulcer may perforate, I operated twice in one year for perforation of the same ulcer. At the first operation 10 hours after perforation a simple closure was done; at the second perforation about a year later a suture and gastroenterostomy was done 6 hours after perforation. He still has some residual symptoms.

Regarding the time that has elapsed after perforation and recovery still be possible, fifteen years ago I saw a young man 36 hours after perforation with all of the symptoms of apparently fatal peritonitis. It seemed hopeless to resort to surgery; this was, however, done, with only closure of the perforation. On opening the peritoneal cavity there was a regular gush of air and fluid. Drains were used but with practically no drainage. He has remained free from symptoms since. So that the result in Dr. Jones' case can be understood; the perforation became sealed off and the peritoneum took care of the infection just as it did in my case of 36 hours' perforation with much more extravasated material still to be taken care of after the perforation was closed by operation.

The diagnosis of an acute perforation is usually obvious. I recall one case where, after a midnight examination, the night supervisor, an experienced Sister, wishing to know what action to take, remarked, "A very sick man, doctor?" "Yes." "An ulcer?" "Yes." "Perforation?" "Yes." "Operation?" "Yes." The general behavior, combined with the board-like rigidity were quite familiar to her. In Dr. Jones' case the picture was not at all so striking and doubt might well be entertained; the radiograph was of striking assistance.

In regard to the incidence of ulcer in Scotland. There are two things that made Scotland famous—whisky and the Bible. Whisky has been given as one of the causes of ulcer. I am not sure whether the reason the Scotch have more ulcers perforate is due to whisky or to economy in the employment of medical assistance.

Dr. C. B. Wright (Minneapolis): Acute perforated peptic ulcer is a surgical condition and should have surgical consideration as quickly as possible. Unfortunately, however, these cases are more often first seen by men with little experience either in the diagnosis or treatment. The reason for this is that perforated ulcers are rare. I have repeatedly heard men in general practice for many years say they have never seen one and it is exceptional to find men, outside of large emergency hospitals, who have seen many of these cases. Forty-three cases at the Minneapolis General Hospital over a period of 10 years and operated on by various surgeons is not a large group when one considers that the Minneapolis General is one of the largest emergency hospitals in the Northwest.

I have seen 9 cases in 27 years of practice. The first was the rarer type of perforated ulcer; that is, a large perforation on the anterior wall. This patient was a young, healthy servant girl without previous symptoms of ulcer, who, after eating a hearty breakfast, collapsed on the stairs and had to be carried to bed. I saw her almost immediately and found her in shock; by that I mean pale, cold perspiration, with a small rapid pulse, and complaining of violent pains in her right lower quadrant. She had vomited, but had not vomited blood. She had dullness in both flanks, generalized abdominal pains with marked rigidity and I felt that she might have a ruptured extra-uterine. She was operated in 2 hours. A large meal consisting of meat, potatoes and bread, was found in her abdominal cavity and a perforation in the anterior wall of her stomach the size of a dollar. Sewing up the opening with a purse-string suture and reinforcing it with mattress-sutures, washing her breakfast out of her abdominal cavity with salt solution was followed by recovery. Her convalescence was complicated by infection of the abdominal wall, right-sided pneumonia, and phlebitis. I saw her 25 years later; she has never had any stomach trouble since and nothing could be found by fluoroscopic examination.

There were two other cases of stomach perforation, one a slow perforating ulcer on the anterior curvature, which was readily diagnosed but refused operation and died a few days later at home of a general peritonitis. A third case was in a young woman where the ulcer perforated into the lesser peritoneum and was cured by draining a large abscess some time later.

I have seen 6 duodenal ulcer perforations. One of these cases had been treated by Osler in 1903 for a dilated stomach; later by Sippy. He was finally operated on by Theodor Bratrud for a sudden perforation, with apparently complete recovery, but died 3 years later of a gastric hemorrhage. Two other cases were not seen until 16 hours after perforation had occurred; both had fairly large perforations and died of general peritonitis after the operation. Another case recovered following an operation for perforation of the duodenum by simply closing the ulcer. He later had several attacks of hemorrhage and died 6 years after the operation in a convulsion. This patient refused hospitalization until the very last, after a long period of vomiting, and died from what apparently was gastric tetany. At autopsy he showed a tremendously dilated stomach, apparently without obstruction because one could easily put two fingers through the pylorus. Two others are living, one 10 and one 20 years after the operation, both having had recurring attacks of ulcer trouble. I have never seen a case of ulcer perforate under any kind of proper medical management. However, cases

have been observed by others. It must be a very infrequent happening.

A previous history of ulcer does not helps us, as the history is difficult to obtain and statistics will show that only about 50 per cent of these cases have had a previous history of ulcer.

Accuracy in the recognition of a surgical abdomen can, in the last analysis, only be determined by the care in the examination of the abdomen and the amount of experience of the examiner. There should be no delay in an attempt to make a refined laboratory diagnosis in these emergency cases and the method of treatment should be determined by the conditions which are present.

My own experience leads me to believe that cases of chronic ulcer in which there has been hemorrhage, penetration, or perforation, should be kept under observation and treated for long periods of time; the longer the better, and by treatment I do not mean milk and powders alone. More important are general hygienic measures such as careful living with plenty of rest and a well-balanced bland diet which contains sufficient vitamins.

Dr. J. T. Christison (St. Paul): It is not my intention to discuss so valuable a surgical paper, but I would like to call the attention of the Academy to the fact that perforating ulcers occur in children not infrequently. I have seen three of them. One was sent into the hospital with a diagnosis of acute appendicitis, another of intussusception, and another of pneumonia. Death occurred in all three, and autopsies were had. Two of them had a perforated ulcer on the posterior wall of the stomach at the pyloric end, and the other had a perforation on the anterior wall about the middle of the stomach.

We must not lose sight of the fact that even in very young babies ulcers do occasionally develop. One of these babies was 9 months, one 11 months, and the other 14 months.

Dr. Robitshek (in closing): I have nothing to add, but wish to thank the members for the very kind reception they have accorded my effort and to thank them as well for their discussions.

The meeting adjourned.

R. T. LaVake, M.D.
Secretary.

EPHEDROL WITH ETHYLMORPHINE HYDROCHLORIDE (LILLY) NOT ACCEPTABLE FOR N. N. R.

The Council on Pharmacy and Chemistry reports that this is a shotgun cough mixture, relying on an opiate for its effect, and on the vogue of ephedrine for sales-appeal. The Council declared Ephedrol with Ethylmorphine Hydrochloride unacceptable for New and Non-official Remedies because it is an unscientific mixture marketed under an unacceptable proprietary name with unwarranted therapeutic claims. (Jour. A. M. A., March 1, 1930, p. 634.)

TRANSACTIONS OF THE MINNEAPOLIS SURGICAL SOCIETY

Stated meeting held March 6, 1930
The President, Dr. S. R. Maxeiner, Presiding.

The meeting was held at the Minneapolis General Hospital and was devoted to clinical case reports presented in the following order:

1. Case reports by Dr. E. A. Regnier.
2. Case reports by Dr. A. A. Zierold.
3. Case reports by Dr. O. J. Campbell.
4. Case reports by Dr. T. H. Sweetser.
5. Remarks by Dr. A. R. Colvin.
6. Remarks by Dr. R. C. Webb.
7. Remarks by Dr. H. B. Sweetser.

Dr. E. A. Regnier: I wish to first present two cases of intracapsular fractures in the neck of the femur. I present these cases, not because of any unusual pathology, but to bring out a few important points in the treatment of this type of fracture.

Case 1.—Female, aged 44, came to the hospital for treatment last August, complaining of pain in the hip, following a fall. Previous history unimportant. (Series of *x*-ray plates shown.) This is a transverse intracapsular fracture of the neck of the femur. Treatment—double plaster spica. You can see from these plates that the anatomical position is good. There is a maximum amount of internal rotation and abduction, which is all-important in this type of fracture. The pictures also show a severe degree of bony absorption, resulting from prolonged encasement in plaster. The plaster in this case was left on for fourteen weeks. Subsequently the patient received physiotherapy, and is now going to be equipped with walking calipers, which we recommend for all of these cases.

Case 2.—This case is practically identical with the previous one, but the treatment was slightly different. The patient was put up in a Thomas Splint in abduction, and as you see from the *x*-ray plate the position was anatomically nearly perfect. Two months later the patient complained of pain in the hip joint. *X*-ray was taken and showed complete displacement of the fracture. This had taken place and the cause was unknown. The patient was then put in a plaster spica, and bony union was obtained after sixteen weeks. She now has excellent functional result and very little shortening. I present this case merely to point out that the treatment of hip fractures is fraught with pitfalls and accidents, and to show the many possibilities that may interfere, and militate against good end-results. We are pretty well committed to the Whitman method of treatment of hip fractures, for the following reasons: it assures against displacement once the cast is applied; it will maintain the fragments in whatever position they may have been reduced; it will assure bony union in a greater percentage of cases than any other conservative method of treatment; it is the only method that can maintain the proper degree of internal rotation, which is necessary in this type of case. It is

not ideal because the prolonged encasement in plaster produces atrophic changes.

We have been using double spica casts in the majority of our cases, because this fixes the pelvis more securely and prevents tilting, and also facilitates moving the patient with less discomfort. The excellent position of the fragments, shown in case two, with subsequent displacement emphasizes the need of frequent *x*-rays, and the greater safety in using the Whitman method of treatment. We recommend a walking caliper for all cases of this kind for a period of two to six months, following bed treatment. It is essential that calipers be carefully measured, for if not properly fitted there will result a coxa vara from too early weight bearing. Non-union is rare by this method of treatment. In fact one case, and the only case in this hospital in the last five years, obtained a firm bony union after eighteen months in a walking caliper.

Case 3.—I want to show this case as an example of a fracture into the knee joint, with an excellent functional recovery, and a very good anatomical result. This man sustained a comminuted fracture of the upper third of the tibia with three definite fracture lines extending into the articular surface of the tibia. He had about three inches shortening. He was treated by the use of skeletal traction; that is, a Steinman pin was put through the os calcis and extension applied for a period of three weeks, during which time the knee joint was frequently flexed. He now has 75 per cent normal motion in the knee joint, and has no shortening, and can do the same work he did before his accident. The important point to stress in the treatment of fractures extending into the knee joint is early motion to prevent ankylosis of the joint.

Case 4.—I wish to show this case as a splendid example of the good results which can be obtained in traumatic surgery by conservative measures, where modern facilities are available. On October 8th a truck backed into this man. He sustained a fracture of the lower third of the right femur, a crushing fracture of the first lumbar vertebra, and a fracture through the acetabulum on the opposite side. Traction was applied to the right femur by the use of calipers for a period of two weeks. At this time the position was very good. Calipers were removed, and soft tissue traction was applied below the knee for a period of five weeks. The other extremity was placed in a Thomas splint with ten pounds of traction for a period of four weeks. The extremity was mobilized each day. (Series of *x*-ray plates shown.) Patient was placed on a Bradford frame in hyperextension, the angle of extension being directly over the first lumbar vertebra. He now has no demonstrable shortening of either extremity. He has no pain in his back whatever, and is perfectly comfortable. He is just beginning to walk around, and we are not urging him to walk a great deal at present. He is getting physiotherapy, and is being treated for diabetes and syphilis. The results, which you see from these plates, are worthy of note, in view of the fact that the man is a diabetic and has had syphilis for twenty years. We do not believe that syphilis plays any important role in the healing of fractures. We believe that the majority of fractures through the lower third of the femur are best handled by the use of skeletal traction. The pull is more positive, requires less weight, and allows for complete mobilization of the joints above and below the point of fracture. Likewise the use of the Thomas Splint for fractures through the acetabulum allows full motion at the hip joint, as to flexion, rotation and abduction. This is particularly important in preventing ankylosis of the hip joint. In crushing fractures of the vertebræ where there is no evidence of paralysis, we believe that complete immobilization on a Bradford frame, with hyperextension of the spine at the point of fracture gives very satisfactory results.

Dr. O. J. Campbell presented the following cases:

Case 1.—The first patient, whom I wish to show, is a man, fifty-nine years of age, who, last October, sustained an intertrochanteric fracture of the left hip. He is of interest only because of the unusual accuracy of the reduction. Buck's extension, with slight abduction, was used from the first and maintained for twelve weeks. For the past five or six weeks there has been no apparatus used, the patient being kept in bed and sent daily to the physiotherapy department. He now has a good range of motion in his hip and is ready to walk with a crutch or upon walking calipers. Only the closest inspection of the film would enable one to detect the fracture line.

Case 2.—The next patient is a boy of eleven years whose right foot had been crushed by a train. The toes were amputated or hanging by shreds of tissue. The skin of the dorsum and the sole of the foot had been completely avulsed. As you can see, in the film, the metatarsals have all been fractured and driven through the sole. The navicular and first cuneiform bones have been displaced laterally. Upon first examination it seemed that nothing short of an amputation would avail. Amputation is particularly unfortunate in a child because of the attendant retardation of growth of the involved extremity. Accordingly a thorough debridement of the foot was done. The toes were removed and the fractures reduced as well as possible. Dakin's tubes were placed in and about the wound and irrigations were started immediately. Serious infection did not occur and after a week his fever returned to normal. We were unable to prevent the development of marked foot drop.

Last week we skin grafted the unhealed areas, using a number of implantation grafts. We did this to get rid of all infection. The next step will be to lengthen the Achilles tendon and get the foot into a good position, following which, it is planned to swing the foot to the opposite thigh and by means of a pedicle flap, give him a fatty pad over the ends of the metatarsals. Finally a steel brace and arch support can be fitted.

We are not too optimistic but if the patient can get a foot which will bear weight, without pain, we can prevent, to a large degree, serious retardation of

growth. In a child of his age the effort does seem worth while.

Case 3.—This fracture of the left humerus was sustained in September of last year. The patient was put to bed and the arm was extended with the forearm flexed to ninety degrees. Extension was maintained for eight weeks and he was discharged with a fair and seemingly adequate callus. After two months he returned with obvious delayed union. The man was anxious to get back to work and the degree of motion at the fracture line was such as to make us feel that, even with a long period of immobilization, union would not occur. As you see on the film there has been a long free fragment. This fragment is firmly united to the proximal shaft. There is no union between the fragment and distal part of the shaft. He was operated upon and very dense scar tissue between the fragments was excised. The ends were freshened and a Parham band was applied around the united free fragment and the distal portion of the shaft. Bone chips were placed in the fracture line and around it. He now has good callus formation. As it is too early to allow him to go without some fixation, we have applied the plaster cast which you see. This cast firmly applied to thorax and shoulder, and maintaining the arm in slight abduction, is the best method we know to immobilize the humerus.

There is a complication of interest. He has a radial nerve palsy. The nerve was intact at operation and the greatest care was exercised in protecting it from injury. Considerable manipulation was necessary and it is believed that there was enough tension put on the nerve to bring about this condition. Sensation has returned but not muscular activity. We know that the nerve is intact and feel satisfied that he will, eventually, get full reurn of function.

Case 4.—This patient is forty-six years of age and was brought into the hospital two weeks ago, completely under the influence of alcohol. He had been found in the neighborhood, with a broken ankle and abrasions about the face.

Twelve hours after admission, the patient failing to void, catheterization was done and 900 c.c. of bloody urine removed. Two hours later 1,300 c.c. was obtained. I saw the patient the next morning, twenty-four hours after admission. The effect of the alcohol had worn off. At this time he had a rigid abdomen, temperature of 99.2 and leukocytosis of 10,000. Catherization again revealed a distended bladder and this time the catheter was retained and fastened in place.

The first diagnosis which suggested itself was ruptured bladder with developing peritonitis. The fact that the bladder had been found distended on several occasions seemed very much against this. Peritonitis from a ruptured viscus was considered unlikely, because of the mildness of his febrile reaction, the low leukocytosis and the absence of gas in the abdomen as demonstrated in the *x*-ray. A diagnosis of intra- or retroabdominal hemorrhage was made. In view of the length of time after the accident (probably about thirty-six hours) and the fact that the patient was improving, it was decided not to operate.

The patient improved steadily for five days. The urine became clear, in spite of which the catheter was retained in the bladder. Gradually he showed signs of paralytic ileus. Extreme distension followed. For a time we succeeded in getting gas through by means of Noble's enemas and pituitrin. He continued to vomit, the blood chlorides dropped to 429, his pulse and temperature rose slightly. On the eighth day, other means failing, we gave him a spinal anesthetic. While under the influence of the anesthesia, pituitrin was given and enormous quantities of gas were expelled. He improved rapidly after this. A daily injection of pituitrin was sufficient to keep him flaccid. He is now getting almost a full diet, and, as you can see, his abdomen is entirely soft and flat. His leukocyte count has never gone above 12,000 and has now dropped to 10,800.

Of interest is the large quantity of fluid needed to maintain his balance during the time he was vomiting so profusely. In one period of twenty-fours he was given 10,500 c.c. of normal salt solution by hypodermoclysis and 1,500 c.c. of 10 per cent glucose intravenously.

The question is—has this man had a perforated bladder. Cystoscopy was done about the fifth day and a small break in the bladder mucosa about 2 mm. long was described. We do not know whether this went through the bladder wall, but it was obviously the source of the hematuria, as the kidney shadows in the *x*-ray had been normal and there was at no time tenderness over the kidneys.

It is our impression that this man has had intra- or retroabdominal hemorrhage, giving him peritoneal irritation and later paralytic ileus.

Dr. Theodore H. Sweetser presented two cases:

Case 1.—As a corollary to my paper read at the November meeting, this patient, who is recovering from an operation for urinary extravasation, is presented to show the remarkable healing properties of the scrotum. As soon as the diagnosis was made, operation was performed—perineal urethrotomy with perineal drainage of bladder, very extensive incision for drainage consisting of bisection of the scrotum and trimming away of all necrotic tissue, and internal urethrotomy of the anterior urethra. The perineal urethrotomy wound has healed. The scrotal wound has shrunk remarkably and is almost covered with skin. Occasional passage of sounds will be needed to be sure of maintaining the full size of the anterior urethra.

Case 2.—A man twenty years old was admitted to the General Hospital in October, 1929, complaining of frequent burning urination, pain in the lower abdomen, and pyuria which had persisted in spite of treatment for gonorrhea for over a year. Physical examination was negative. Urine was of low fixed specific gravity, and showed pus and at times a few blood cells. P.S.P. tests and blood chemistry showed a very severe renal

insufficiency. After careful study on the medical service I was asked to examine him cystoscopically.

The bladder appeared normal, and the only clue to the diagnosis lay in the right pyeloureterogram. The moth-eaten pyelogram with extensions into the renal cortex and the irregularly dilated ureter were strongly suggestive of tuberculosis.

Although tubercle bacilli were not found in the urine at or even just after this cystoscopy, and the guinea pig inoculated with the urine obtained at cystoscopy failed to develop the disease, still one bacillus was found in the urine a week after the cystoscopy, and organisms have been found repeatedly since, though not in all specimens.

A second cystoscopy was done nine days after the first; there were at that time a few minute nodules in the musosa just below each ureteral orifice. The left pyeloureterogram shows filling defects, extensions into the renal cortex, and a marked irregular dilatation of the ureter.

The diagnosis, then, was definitely bilateral tuberculosis of kidneys and ureters with minimal involvement of the bladder. He was sent to the Glen Lake Sanatorium, where he now is.

From this case we learn that a diagnosis of renal tuberculosis may be difficult even with every facility at hand for its determination. Also we are warned that we should search for some reason, when a case does not respond to treatment in a reasonable time. This man may have had gonorrhea in July, 1928, but surely tuberculosis was the cause of his pyuria and urinary symptoms long before October, 1929.

Dr. A. R. Colvin: I didn't have the remotest idea of coming over here to discuss anything. I received a very kind message to come and attend a clinical meeting and I have enjoyed it immensely. The thing that has impressed me here all evening has been the eminently conservative manner of treatment and the good results. That knee case that was shown a short time ago was an evidence of the careful persistent keeping after a fracture which is so necessary in the treatment of fractures.

Before saying anything about fractures, I would like to recite a little experience with urinary extravasation, which is always a most interesting subject. As a third year student, I went out into the Alberta prairies to take the practice of another physician and just before he left he opened an abscess in a man's scrotum. The patient came back a short time later and I was horrified to find that the man was passing urine through his abscess opening. I had had then no experience along this line, but it happened that the physician whose place I was taking had a very good library and in looking through the literature I found a very valuable article by Sir Henry Thompson. One of the conditions that he referred to was a condition of multiple sinuses of the scrotum as a result of extravasation of urine due to stricture. These cases, when neglected, present themselves with multiple sinuses and when the patient urinates urine is passed through these various sinuses. Sir Henry Thompson in describing this condition called it a "watering pot scrotum." My patient had evidently a stricture of large caliber behind which developed a periurethral abscess and a consequent extravasation of urine. I was fortunate enough to be able to pass a catheter into the bladder and in this way the urethral fistula closed. However, perineal section is usually required and always in the old neglected cases.

Another case which I remember very clearly is that of a patient who had lost the entire scrotal skin and almost the entire skin of the penis as a result of cellulitis of the scrotum. The skin is, however, usually not entirely lost. After a certain amount of destruction has taken place the remaining skin retracts up around the root of the penis. After a healthy condition of granulations has been established, the skin is gradually pulled down again and in a surprisingly short time the scrotum and penis become again covered with skin.

The thought that occurred to me about fractures as I listened to these cases was that I wondered why the Society hadn't spent more time discussing fractures of the neck of the femur. It seems to me that with the talent you have here you could discuss that subject for a long time. The case that interested me most was the case of the woman who walked in here whose *x*-ray pictures showed a great deal of absorption of the neck and still she had an excellent functional result. I have at present a patient whose subcapital fracture I put up in the approved Whitman position. I have *x*-ray pictures taken at about the end of the month showing absolute anatomical position. You can hardly tell there has been a fracture. A picture taken at the end of three months showed almost complete disappearance of the neck. There seems to be a growing conviction that absorption of the neck does occur even in the presence of correct treatment. Lorenz insists, however, that before we accept the condition of absorption in any given case we must be sure that we have correct and maintained reduction. It will thus be important, where our radiographs show good reduction, that we assure ourselves by frequent pictures that this is maintained. Provided that absorption has occurred is there still any chance of union? Speed, of Chicago, writing of non-uniting fractures of the neck insists on remanipulation and again putting up in a cast for a long time. Inasmuch as just in these cases of complete absorption reconstruction operations are less satisfactory it becomes important to follow Speed's advice. Anschutz, reviewing at great length in "Die Engebnisse der Chirurgie and Orthopoedie" the whole subject of fractures of the neck of the femur, acknowledges Whitman's method as the correct manner of treatment. He also cites cases with illustrations where prolonged treatment in cases with absorption of the neck has resulted in good functional result and in the radiograph shows a stable structural result.

It would seem important therefore to lay stress upon the persistent and continued treatment of the neck of the femur even in the presence of delayed union.

Dr. H. B. Sweetser: My experience goes back to before the day of the *x*-ray, when we were obliged to depend entirely on clinical methods for diagnosis and a check-up on the results of treatment; and the results frequently left much to be desired. I was therefore very much interested in this series of *x*-ray plates, showing the position of the fragments before and after reduction, and, at intervals afterwards, whether reduction has been maintained, and if the progress made in ossification is satisfactory.

The *x*-ray and improved refinement in aseptic technic have aided immensely in the management of fractures and in the results attained.

Up to twenty years ago intracapsular fracture of the femur doomed the patient to non-uion and consequent loss of power to walk in almost one hundred per cent of the cases; today, by the Whitman method or by bone pegging, we may hope for union in a large proportion of the cases. In fractures entering a large joint, when the roentgenogram shows that the fragments cannot be put and held in perfect alignment, we no longer hesitate to open the joint and nail the fragments in their exact absolute relationship to each other.

The business meeting of the Society was held immediately following the program.

The election of officers for the ensuing year was held with nominations from the floor as no preliminary nominating committee had been appointed.

For the presidency the name of Dr. E. T. Green was presented by Dr. S. H. Baxter with a second nomination of Dr. A. T. Mann by Dr. E. A. Regnier. Dr. Mann was elected by a vote of 7 to 6.

For vice-president Dr. Theodore Sweetser was nominated and unanimously elected.

Dr. H. O. McPheeters was continued as secretary-treasurer, having been elected a year ago for a period of three years.

Dr. J. M. Hayes was re-elected to the council for a five-year term and Dr. Owen Wangensteen was elected to fill the unexpired term of Dr. Theodore Sweetser.

Drs. Tom Kinsella, O. J. Campbell, and R. P. Caron were elected to membership in the society.

There was a general discussion as to enlarging the membership of the society and whether or not surgical specialists might be included. The final decision was to continue as in the past, restricting membership to those who do only "general surgery" as was the idea when the organization formed.

The meeting adjourned at 10:30 p. m.

H. O. McPheeters, M.D.
Secretary.

Stated meeting held May 1, 1930

The President, Dr. S. R. Maxeiner, Presiding.

The Minneapolis Surgical Society met Thursday evening, May 1, at the home of the president, Dr. S. R. Maxeiner.

The society offers two prizes each year for the best thesis on the subject of clinical surgery. The essays this year were of an unusually high standard and quality and the competition was more keen than ever. Essays winning first and second awards were read at this meeting.

The essay winning first prize was written by Mr. Charles Rea, a senior in the University of Minnesota Medical School, on the subject of "Malignancy of the Undescended Testicle." This showed a large amount of original research work combined with a most complete and thorough résumé of the literature on this subject. It was a most valuable contribution to the profession.

The second prize was won by Dr. Evelyn G. McLane of Sleepy Eye, Minnesota. Dr. McLane made a complete résumé of all goiter cases which had been operated on at the New Asbury Hospital during the past five years. This brought out many very interesting facts and showed that the mortality rate at one of the best private hospitals was equal to that of the best clinics in the country.

The retiring president, Dr. S. R. Maxeiner, gave the address of the evening. This was on "Constructive Criticism for the Society." The work of the year was reviewed generally and plans outlined for the coming year.

CONSTRUCTIVE CRITICISM

Stanley R. Maxeiner, M.D., F.A.C.S.

Mr. Chairman and Members of the Minneapolis Surgical Society:

Permit me to thank you for the honor which was conferred upon me when you elected me to your presidency. I also wish to thank you for your coöperation throughout the year as I fully realize that what success has been attained could not have been effected otherwise. Especially deserving of thanks are those members who have furnished the programs, those who have served on the Council, and, most of all, our efficient secretary, Doctor McPheeters, whose efforts have been untiring and spontaneous. I shall attempt to follow the precedent established by our last two past presidents by furnishing constructive remarks relative to the past and future of our society.

During the past year we have had eight meetings as usual and one excellent clinic. With an active membership of 36, we have had an average attendance of 18, or 50 per cent, which compares favorably with that of other organizations to which I belong. Two candidates have not given their initiation theses within the time limit and, as a result, have not become members. Several members have not been especially active, while three new members have been elected and several other applications have been received. Although this society is still very young, we are building our reputation and I sincerely hope that in the near future it will be such an honor to be within its folds that every surgeon in Minneapolis will feel that he can ill afford not to belong.

Repeatedly discussion has occurred relative to including members of other branches of surgery, such as orthopedics, gynecology and urology, among our eligibles, but to date no action has been taken. The writer believes that the increase in members would be small but that many benefits might follow, from contact between our general surgeons and representatives of

these specialities. It is of such importance that it could well be given adequate time for ample discussion and final settlement.

At the suggestion of Doctor Webb, a suitable seal has been adopted and, as you have noted, has been used as a letterhead. This custom has been followed by other societies and lends certain dignity to our correspondence and notices.

Our constitution and by-laws drawn up in 1922 have been repeatedly amended so that one refers to them with difficulty. The original printed copies have been expended and it would seem advisable to have a committee to republish the revised articles. A copy should accompany the letter notifying new members of their election.

A committee composed of one or more members on each hospital staff to report interesting and instructive cases was appointed and I believe should be a valuable asset. Their work should be encouraged.

In 1927, your society adopted a resolution offering a prize for the best essay on a subject in the field of clinical surgery, students at the University of Minnesota working for the degree of Doctor of Medicine, or any interne in a Minneapolis hospital being eligible.

In 1929, one essay was offered and the prize was awarded to Doctor M. E. Knapp on "Afferent Nerve Supply of Blood Vessels." This, the second year of the prize essay contest, six essays have been submitted. Members of the Council who have had the opportunity to read these essays must all agree that they are of high calibre indeed, displaying a tremendous amount of effort in reviewing the literature and hospital records. From these six essays, two have been selected as winners, but the other four are of such excellent quality that it has not been an easy matter to pick the winners. I believe that all of the contestants who have not been fortunate enough to receive a prize award should be sent a letter by the secretary commending them upon the excellence of their work and notifying them that their paper has earned honorable mention. I believe that this would be a stimulus for the presentation of similar papers next year.

I have personally been so well pleased with the result of our prize essay contest this year that I believe in fostering this effort alone our Society justifies its existence.

I would also recommend that, hereafter, all essays be submitted with the understanding that if they are particularly worthy they may be published at the discretion of the Council even though they do not happen to win a prize.

This point brings up the matter of publication of the society's proceedings. Unfortunately all of the membership was not present at the discussion of this matter following the April meeting and as a result I am referring to the matter again. There is no question but what the standard of our scientific papers and the discussion of these papers will be of a higher standard when it is known that they are to be published. The published transactions of the New York and Philadelphia Societies furnish some of the very best material published in the surgical journals. All of us pick up the *Annals of Surgery* and turn to the transactions because we have a feeling that we will find something good. I believe that this society has membership with adequate material and sufficient brilliancy to render the same service through Minnesota Medicine.

One of the most important tasks confronting our officers is the arrangement of programs. Well do we know that attendance will be largely based upon the quality of the program at a given meeting, and how often have we seen nearly a full attendance when the speaker is a guest from another city, although his presentation may show no greater brilliancy than that displayed by some of our own members. This fact alone should be adequate reason, however, to invite prominent outsiders to make special trips to Minneapolis and to be on the alert to obtain their services when they may be passing through our city.

Since our first meeting in March, 1922, fifty-six prepared papers have been given, or an average of one per meeting. Of these, eighteen, or one-third, have been presented by invited guests. During the same interval, about the same number of members have reported cases of interest. Personally, the writer believes that many surgical truths are best illustrated by the presentation of a well prepared case report. The fact that case reports predominate would support this conclusion.

During the past few weeks I have talked to a number of members relative to the future policy of the society in regard to programs and, judging from suggestions made, combined with the fact that the American College of Surgeons, the Inter-State Post-Graduate Medical Association, the State Medical and others have considered two subjects of prime importance, namely traumatic surgery and cancer, I believe that it might be well for us to consider a whole series of papers in the nature of a symposium on either subject.
